1 Abstract

In order to study circuit complexity classes within NC^1 in a uniform setting, we need a uniformity condition which is more restrictive than those in common use. Two such conditions, stricter than NC^1 uniformity [Ru81,Co85], have appeared in recent research: Immerman's families of circuits defined by first-order formulas [Im87a,Im87b] and a uniformity corresponding to Buss' deterministic log-time reductions [Bu87]. We show that these two notions are equivalent, leading to a natural notion of uniformity for low-level circuit complexity classes. We show that recent results on the structure of NC^1 [Ba89] still hold true in this very uniform setting. Finally, we investigate a parallel notion of uniformity, still more restrictive, based on the regular languages. Here we give characterizations of subclasses of the regular languages based on their logical expressibility, extending recent work of Straubing, Thérien, and Thomas [STT88]. A preliminary version of this work appeared as [BIS88].

2 Introduction

2.1 Circuit Complexity

Computer scientists have long tried to classify problems (defined as Boolean predicates or functions) by the size or depth of Boolean circuits needed to solve them. This effort has

developed into the field of *circuit complexity theory*, where classes of problems are defined in terms of constraints upon circuits solving them. This study has become more important recently because of the connections between size and depth of Boolean circuits and number of processors and running time on a parallel computer (see Cook [Co85] for a general survey).

The complexity class NC^1 consists of those Boolean functions (functions from $\{0,1\}^*$ to $\{0,1\}$) which can be computed by circuits of fan-in two and depth $O(\log n)$. That is, f is in NC^1 if for each n there is a circuit C_n which computes f correctly on inputs of size n, and each C_n has depth at most $c \log n$ for some constant c. (This is "non-uniform" NC^1 — we discuss uniformity below.)

Problems in NC^1 are usually considered particularly easy to solve in parallel, and thus NC^1 is considered a "small" complexity class (for example, it is the smallest of the ten surveyed by Cook [Co85].) But it lies above a certain frontier — our current techniques for proving lower bounds on circuit complexity have not allowed us to prove any significant problems to be outside of it, for example, even any NP-complete problems. This motivates a study of subclasses of NC^1 which might lie below this frontier, in an effort to develop new techniques and new understanding.

There is a subclass of NC^1 for which separation results are known. AC^0 is the class of problems which have circuits of polynomial size and constant depth in a model with unbounded fan-in. Furst, Saxe, and Sipser [FSS84] and independently Ajtai [Aj83] proved that the exclusive OR function is not in AC^0, separating this class from NC^1. Later work has attempted to extend the frontier upward from AC^0 by proving lower bounds for more powerful subclasses.

Razborov [Ra87] considered the extension of AC^0 obtained by also allowing unbounded fan-in exclusive OR gates, and showed that the majority function (defined by $f(x_1, \ldots, x_n) = 1$ iff the majority of the x_i are 1) is not in this class. Barrington [Ba89] defined the class ACC (AC^0 with counters), which further extends Razborov's class by allowing unbounded fan-in gates which count their inputs modulo some constant. He conjectured that the majority problem was not in ACC, and hence that $ACC \neq NC^1$. This remains open, though Smolensky [Sm87] has proved some important partial results in this direction, introducing what promises to be a powerful new proof technique. Existing techniques have been unable to show even an NP-complete problem to be outside of ACC.

Between ACC and NC^1 is another class which has excited considerable interest. A *threshold gate* counts its Boolean inputs which are 1 and compares the total with some predetermined number to determine its output. This generalizes unbounded fan-in AND (threshold = in-degree), OR (threshold = 1), and majority (threshold = half the in-degree) gates, but any threshold gate can be built out of these three basic types. TC^0 is the class of problems solvable by families of circuits of unbounded fan-in threshold gates, where circuit depth is bounded by a constant and circuit size by a polynomial in the input size. As individual threshold gates can be simulated in NC^1, $TC^0 \subseteq NC^1$ (also, it is fairly easy to see that $ACC \subseteq TC^0$). Considerable recent work has dealt with TC^0, some of it motivated

by analogies with neural computing [PS88,HMPST87,Re87].

2.2 Uniformity

In their non-uniform versions these circuit complexity classes contain problems which are not computable at all in the ordinary sense (e.g., any unary language is in AC^0). To compute with a circuit family we must be able to construct the circuit for each input size. We may loosely define a *uniform* circuit family as one in which the behavior on all inputs, of any size, is specified by a single finite bit string. A weak uniformity condition would be to allow this string to be the description of a Turing machine which on input n produces the circuit C_n. Since we are concerned with complexity and not just computability, a better definition places resource restrictions on the Turing machine.

A circuit family $(C_1, C_2, \ldots)$ is *P-uniform* if the circuit C_n can be constructed from n in time polynomial in n. It is *L-uniform* if C_n can be constructed using space $O(\log n)$. These definitions suffice to prove the classical result that "uniform" circuits of polynomial size are equivalent in computing power to Turing machines using polynomial time. In fact, the same proof shows the result either for P-uniform or L-uniform circuits, showing these two classes equivalent to each other.

There is a sense in which the L-uniform version of this result is more satisfying than the P-uniform one. In the latter case, if we believe $P \neq L$, we know that we have isolated an important fact about circuits and machines. That is, the polynomial-size circuits were able to simulate the polynomial-time machines on their own, without the potential help of a polynomial-time machine used to construct them.

As we study a given circuit complexity class, we would like to use a uniformity condition which separates these two sources of computational power. That is, we want to allow strictly less power to construct the circuits than the circuits themselves posess. In this paper, we explore a variety of conditions suitable for the study of the classes AC^0, ACC, TC^0, and NC^1.

There is a reasonable (though complicated) notion of NC^1 uniformity ("U_{E^*} uniformity") due to Ruzzo [Ru81] (see also [Co85]) which has the consequence that NC^1-uniform NC^1 is equivalent to alternating logarithmic time (modulo appropriate conventions on the alternating Turing machines). This definition is based not on constructing the circuit but on answering certain classes of questions about it in alternating logarithmic time. Most proofs involving P- or L-uniform circuit families go through under this definition, making it a good tool for studying complexity classes above NC^1. But to go within NC^1 itself, we will require new notions, still more restrictive.

We note that one may still speak of, say, P-uniform NC^1, and that this may be a class of considerable interest. At least by analogy, it represents problems for which a very fast chip could be manufactured by a sequential process in reasonable time. Many natural problems have been shown to be in P-uniform NC^1 and are not known to be in more uniform versions

[BCH84,Re87]. Recent work by Allender [Al87] shows P-uniform NC^1 to be a fairly robust class, with a number of equivalent definitions.

3 Summary of Results

In this paper we consider three candidates for a suitable notion of uniformity within the class NC^1. Each is based on a subclass of NC^1 — the computational power used in specifying the circuits in a family is limited to this subclass. In Section 4 we make precise the definitions of the circuit classes already mentioned and the ways in which circuits are specified.

The first notion is based on Immerman's theory of expressibility as a complexity measure [Im87a,Im87b]. The basic complexity class in this scheme is the class FO of languages which can be expressed by first-order formulas in a certain formal system, to be explained in detail in Section 5. First order formulas can be evaluated by AC^0 circuits of a particularly regular form, so that FO is a uniform version of AC^0.

In Section 6 we will examine classes defined by first-order formulas which include new types of quantifiers, giving uniform versions of ACC, TC^0, and NC^1. Whereas ordinary quantifiers express whether an instance or all instances of the quantified variable are satisfying, the new quantifiers will perform some other function on the sequence of truth values given by the sequence of instances. For example, we will define quantifiers which can count the satisfying instances modulo some constant, determine whether the majority of the instances are satisfying, or even interpret the truth values as elements of some finite group and multiply them. In fact, we will define quantifiers for any function meeting a certain technical condition, that of being "monoidal". The expressibility scheme extends to even larger complexity classes through the use of "syntactic iteration" in formulas — see for example [Im87b].

In Section 7 we introduce our second notion of uniformity. This is based on deterministic logarithmic time and the log-time hierarchy, used extensively in the proof by Samuel Buss [Bu87] that the Boolean formula value problem is in alternating logarithmic time (i.e., NC^1-uniform NC^1). To make these classes meaningful, we must allow random access for the read-only input tape of the Turing machine. Buss restricts his NC^1 circuits to be Boolean formulas (fan-out 1) and thus is able to use a uniformity condition equivalent to Ruzzo's, but simpler to state. His condition is that a certain "formula language" be decidable by an alternating Turing machine in time $O(\log n)$, but we will consider families in which the same language is decidable by a *deterministic* Turing machine within this time bound. We will define a notion of "expression" which will extend the notion of "infix Boolean formula" to allow operators of unbounded fan-in and operators for other functions besides AND and OR (such as modular counting, majority, and group multiplication). We will also consider families of circuits (with gates for these additional functions) for which certain queries can be answered by a deterministic log-time Turing machine. These new notions (implicit in

Buss' use of deterministic log-time reductions) are additional candidates for a uniformity notion within NC^1.

In Section 8 we prove our main technical result, which directly relates our first two notions of uniformity. We show that the computation of a deterministic log-time Turing machine may be simulated by a first-order formula, i.e., that the language of strings accepted by a particular log-time machine is first-order expressible. From this we show that the class FO is equal to the log-time hierarchy used by Buss.

In Section 9 we prove our main result, that our first two notions give a robust definition of uniformity for these circuit complexity classes:

Theorem 9.1: Let $\mathcal{F}$ be any set of monoidal functions. The following are equivalent definitions of "L is in uniform $AC^0[\mathcal{F}]$" (e.g., AC^0, ACC, TC^0, or NC^1):

1. L is first-order definable using $\mathcal{F}$ quantifiers.
2. L is recognized by a $DLOGTIME$-uniform family of constant-depth, polynomial-size circuits with gates for AND, OR, and a finite set of functions in $\mathcal{F}$.
3. L is recognized by a first-order definable family of such circuits.
4. L is recognized by a $DLOGTIME$-uniform family of constant-depth, polynomial-length expressions using AND, OR, and a finite set of functions from $\mathcal{F}$.
5. L is recognized by a first order definable family of such expressions.

For NC^1 and above, these definitions also coincide with the earlier notion of NC^1 uniformity [Ru81,Co85].

Given a robust notion of uniformity which can operate within NC^1, we then proceed in Section 10 to examine the resulting uniform classes. A natural question to ask is whether known results about the structure of NC^1 hold true under these definitions. We show that Barrington's construction [Ba89], of NC^1 circuits to simulate branching programs, can be carried out in this setting. This is an improvement over the original argument under NC^1 uniformity, as this appeared to require the full power of $ALOGTIME$. This construction gives the following stronger version of the theorem (See [Ba89] or [BT88] for definitions and the relevance of solvability of groups and monoids):

Corollary 10.2: The word problem for S_5 (or for any non-solvable monoid) is complete for uniform NC^1 under uniform AC^0 reductions, using this new notion of uniformity. Therefore, uniform branching program families of width 5 and polynomial size recognize exactly uniform NC^1.

The third notion of uniformity we consider, in Section 11, uses the regular languages as our basic subclass of NC^1. It arises when we consider the fact that both the other notions allow reference to individual bits of a binary integer. A log-time Turing machine can do this

by indirect addressing, and Immerman's logical system contains an explicit atomic predicate $BIT(i,j)$ which gives the i^{th} bit of the binary expansion of j. What sort of more restrictive uniformity notion do we get by removing this ability from the logical system?

There are four complexity classes to consider here, the languages expressible by first-order formulas using each of our four types of quantifiers. The first two give us well-studied subclasses of the regular languages. The languages expressible by first-order formulas without BIT are exactly the *aperiodic* or *group-free* regular languages, as first proved by McNaughton and Papert [MP71]. When we add counting quantifiers to get a uniform version of ACC, we get exactly the *solvable* regular languages, as shown recently by Straubing, Thérien, and Thomas [STT88].

The two more powerful quantifier types, majority quantifiers and group multiplication quantifiers, yield uniform versions of TC^0 and NC^1 in the presence of BIT. Thus adding them without BIT can be thought of as giving even more uniform versions of these classes. We investigate the classes of languages expressible in these two situations and show that in each case we get a previously encountered language class:

Theorem 11.2: The BIT predicate can be defined by a first-order formula with majority quantifiers (in this version without BIT as a primitive). Hence this version of uniform TC^0 is the same as the other.

Theorem 11.6: A language can be expressed by a first-order formula with group quantifiers and ordinary quantifiers (without BIT) iff it is regular.

These two cases are very different, as in the latter case we find that this more restrictive notion gives us a different class. That is, the ability to look at individual bits is crucial to the relationship between finite groups and NC^1. In Section 12 we explore this issue further, employing classical results on the algebraic structure of finite automata. (See, e.g., [Ei76], [La79], or [Pi86] for background and terminology.)

A finite automaton defines a *monoid* of transformations on its states — a set of functions with an associative operation (functional composition) and an identity (the identity function on the states). The behavior of an automaton on a given input string is a transformation which is the product of the transformations corresponding to each input letter. This mapping from strings to behaviors contains the essence of the automaton's computation. It can distinguish two input strings only by mapping them to different behaviors. We say that a language is recognized by a monoid M if it is recognized by an automaton that has M as its underlying monoid of transformations.

In general an automaton can recognize more languages if this monoid is larger or more complicated. A structure theory of finite monoids has been developed (originally by Krohn and Rhodes [KRT68]) generalizing the structure theory of finite groups. Just as all groups can be decomposed into simple groups (the composition factors of the Jordan-Hölder theorem), all monoids can be decomposed into simple groups and monoids containing no nontrivial groups.

We are able to characterize languages expressible with group quantifiers in terms of the structure of monoids that recognize these languages. In the logical language with BIT, all nonabelian simple groups are equivalent — with quantifiers for any of them we can express any NC^1 predicate and thus multiplication in any other group. But without BIT we can prove that these building blocks are independent, i.e., that using one non-abelian simple group we cannot express another.

Theorem 12.1: Let $\mathcal{G}$ be a family of finite groups. A language L can be expressed using quantifiers for groups in G (and ordinary quantifiers) iff it is regular and is recognized by a monoid M such that every simple group occurring in the decomposition of M is a composition factor of a group in $\mathcal{G}$.

We conclude in Section 13 with some open problems and directions for further research.

4 Definitions of NC^1 and subclasses

We now make precise the definitions of the circuit families and circuit complexity classes which we have been discussing. A *Boolean circuit* is a labelled directed acyclic graph whose nodes, called *gates*, are each assigned a value from $\{0,1\}$ which is a function of the values of its predecessor nodes. The source nodes or *inputs* are each labelled with the name of one of n *input variables* or its negation, and there is a single sink node, the *output*. Each internal node is labelled with a Boolean function of its inputs. Later we will consider extensions to this model where other functions of the inputs are allowed at internal nodes. The whole circuit computes a function from $\{0,1\}^n$ to $\{0,1\}$. The *size* of a circuit is the number of its nodes, and the *depth* is the length of the longest path from an input to an output.

A *circuit family* is a set consisting of a circuit C_n for each integer $n > 0$, and computes a function from $\{0,1\}^*$ to $\{0,1\}$ (or equivalently, recognizes a *language*, a subset of $\{0,1\}^*$). The size and depth of a family are functions of n. We will define different classes of languages by placing various bounds on these size and depth functions, and varying the types of gates allowed. The most common gates will be the AND and OR functions, with the additional variation that we may restrict the fan-in of the gates to two or not restrict it at all.

In order to define various uniformity conditions, we will have to fix a scheme for describing circuits. Let $\langle C_n : n > 0 \rangle$ be a circuit family where each node in each circuit is given a number, unique for that circuit. If the circuit contains gates computing noncommutative operations (as will some of our examples), we insist that the children of a node be numbered consistently with the order of evaluation. Then the *direct connection language* of the circuit family is the set of all tuples $\langle t, a, b, y \rangle$ where a and b are numbers of nodes in C_n, b is a child of a, node a is of type t, and y is any string of length n. (The string y is added to give the query string the proper length. An alternate approach would be to replace y with a binary representation of n and alter as necessary the resource bounds for computing queries, as in [BCGR89].) If $\mathcal{C}$ is any class of languages, a circuit family is said to be *$\mathcal{C}$-DCL-uniform* if its direct connection language is in $\mathcal{C}$.

A *Boolean formula* is a string denoting a special kind of Boolean circuit, a tree whose gates are binary ANDs and ORs. The circuit is represented in the usual infix notation (see, e.g., [Bu87]), with the addition of a special "space character" which may be inserted anywhere with no effect on the formula's meaning. This will allow us more freedom in formatting our formulas, but will not cause us any more difficulty in parsing them. We define a formula family to be similar to a circuit family - - a set consisting of an n-input formula for each n, and has size and depth functions like those of a circuit family.

A *general expression* is also a string denoting a circuit which is a tree, but the circuit may have gates of arbitrary fan-in and may have gate types other than AND and OR. The string for a particular gate consists of an identifier for the gate type and strings for each of the node's children, enclosed by parentheses and separated by commas. The length of an expression is the number of characters in the string, and its depth is the depth of nesting. As with Boolean formulas, we allow a space character to occur at any point with no effect on the meaning. We define expression families in the same way as circuit or formula families. The *formula language* of a formula family (or the *expression language* of an expression family) is the set of tuples $\langle c, i, y \rangle$ for which $|y| = n$ and the i^{th} character of the n^{th} formula or expression is a c. Again, a formula or expression family is said to be C-uniform if its formula or expression language is in C.

We will now define our basic circuit complexity classes in their non-uniform versions. The class NC^1 is defined as those languages recognized by families of circuits of AND and OR gates of fan-in two and depth $O(\log n)$. The class AC^0 is defined as those languages recognized by families of circuits of AND and OR gates with arbitrary fan-in, size $n^{O(1)}$, and depth $O(1)$. (See, e.g., [Co85] for more on the classes NC^i and AC^i.) It is easy to show $AC^0 \subseteq NC^1$, and the inclusion is known to be strict [FSS84, Aj83].

Both NC^1 and AC^0 have equivalent definitions (in their non-uniform versions) by families of expressions. NC^1 is the class of languages recognized by families of Boolean formulas of polynomial length [Sp71] or by families of polynomial length and depth $O(\log n)$. AC^0 is the class of languages recognized by families of expressions of polynomial length and constant depth, using the unbounded fan-in AND and OR operations.

Given a function f from $\{0,1\}^*$ to $\{0,1\}$, the AC^0 closure of f is defined as those languages recognized by families of circuits of AND, OR, and f gates with arbitrary fan-in, size $n^{O(1)}$, and depth $O(1)$. An f gate with m inputs computes the restriction of f to $\{0,1\}^m$. Similarly we may speak of the AC^0 closure of a family of functions. As above, an equivalent definition can be given in terms of expressions with operations drawn from a particular family of functions.

We define $AC^0(q)$ to be the AC^0 closure of the functions $MOD(q,a)$ which return 1 iff the sum of the inputs is equal to a modulo q. The class ACC is the union of $AC^0(q)$ for all $q \geq 2$. It is easy to see that $ACC \subseteq NC^1$, and this inclusion is conjectured to be strict [Ba89]. Partial results are known in this direction. The function MAJ, which returns 1 iff the input has more 1's than 0's, is in NC^1 but was shown to be outside $AC^0(2)$ by

Razborov [Ra87] and outside $AC^0(p)$ for all primes p by Smolensky [Sm87]. Smolensky also showed $MOD(q,a) \notin AC^0(p)$ for p prime and q not a power of p.

We define TC^0 to be the AC^0 closure of MAJ (cf. [HMPST87]). This is equivalent to the class of languages recognized by circuits of polynomial size and constant depth made up of arbitrary threshold gates (cf. [PS88]). TC^0 is a subset of NC^1, and it is conjectured [HMPST87] that the inclusion is strict. A language is said to be *complete* for NC^1 under AC^0 reductions if its AC^0 closure is NC^1. Languages known to be complete for NC^1 include the Boolean formula value problem [Bu87] and a class of algebraically defined languages, the *word problems* for any non-solvable group [Ba89] or monoid [BT88], which we now describe.

A monoid is a set with an associative binary operation and an identity (groups are a special case – monoids with inverses for all elements). Given a finite monoid M, a representation of the elements of M as binary strings, and a "punctuation" scheme so that sequences of elements of M can be denoted, the word problem for M and $a \in M$ is the set of strings denoting sequences which multiply to a. If M is represented as a set of transformations of a set of w elements, this word problem is equivalent to a problem about certain directed graphs of *width* w, that is, where the nodes are partitioned into an ordered set of levels each of size w, and each directed edge goes from a node in one level to a node in the next level. We represent the word problem by using the edges out of one level to represent the transformation corresponding to each monoid element, and asking questions about the existence of paths from the first level to the last. It has been shown [Ba86, Ba89, BT88] that determining the output of a family of such *branching programs* of constant width and polynomial size is equivalent in difficulty to these word problems. This has led to the proof that such programs of width 5 recognize exactly NC^1, and to characterizations of the classes AC^0 and ACC.

5 The First-Order Framework

Immerman has been studying the complexity of *expressing* properties in first-order logic as opposed to the complexity of *checking* whether or not an input has a given property. In this framework, inputs are first-order structures. First-order logic is a familiar language for expressing properties. Here we present a sketch of the relevant definitions. See [Im87a] or [Im87b] for more detailed definitions and background information.

We will use formulas to express properties of Boolean strings, though the system easily extends to express properties of graphs or of more complicated structures. Our logical language will have variables which range over positions in the string, that is, numbers from 1 to n for some n. We will have constant symbols for 1 and n and binary predicates $=$ and $<$ on numbers. We access the input by a unary predicate $X(i)$, whose value is the i^{th} bit of the input string. Finally, for technical reasons, we include the binary predicate $BIT(i,j)$ on numbers, which holds iff the i^{th} bit in the binary expansion of j is a one.

We now define our *first-order language* $\mathcal{L}$ to be the set of formulas built up from the given relation symbols and constant symbols: $=, \leq, BIT, 1, n, X(\ )$, using logical connectives: $\wedge, \vee, \neg$, variables: $x, y, z, ...$, and quantifiers: $\forall, \exists$. A *sentence* in $\mathcal{L}$, i.e., a formula with no free variables, expresses a property of strings — a given string determines values of n and of $X(i)$ for each i, and these values make the formula either true or false. Define FO to be the set of all languages expressible by sentences in $\mathcal{L}$.

This system can be augmented in a number of interesting ways. One can add new constant and relation symbols to speak about more complicated structures than strings. When we deal with regular languages later, it will be convenient to speak of strings of inputs over an arbitrary finite alphabet A rather than just $\{0,1\}$. We do this by replacing the atomic predicate $X(\ )$ with atomic predicates $C_a(\ )$ for each $a \in A$, such that $C_a(i)$ is true iff the i^{th} input character is an a. To take another example, the language of graphs would replace $X(\ )$ with a binary relation symbol $E(\ ,\ )$ for the edge predicate on pairs of vertices. One can add a least fixed point operator (LFP) to first-order logic to formalize the power of defining new relations by induction. Immerman and Vardi independently showed that the language $(FO + LFP)$ is equal to polynomial time [Im86, Va82]. Immerman also considered the addition of a transitive closure operator (TC) to first-order logic, and showed that $(FO + TC) = NSPACE(\log n)$ [Im86, Im88].

Recently Immerman has observed that first-order inductive definitions of depth $t(n)$ (IND$[t(n)]$) express exactly the same properties as those checkable in time $t(n)$ on a concurrent read, concurrent write, parallel random access machine having polynomially many processors (CRAM-TIME$[t(n)]$) [Im89]. An immediate corollary is,

Fact 5.1 (Im89) *FO = CRAM-TIME$[O(1)]$.* ∎

It was previously known that the non-uniform versions of FO and CRAM-TIME$[O(1)]$ are equal to non-uniform AC^0 [Im89,SV84]. This, coupled with the above Fact, suggests the class FO as a natural candidate for the role of uniform AC^0. We will give some interesting evidence for the robustness of this uniformity definition.

In the next section we will also augment this framework by adding new quantifiers to the language which express operations not definable in the original FO. In particular, we will define quantifiers which will correspond exactly to the new gate types (modular counting, majority, and group multiplying) which we added to the Boolean circuit model to give the non-uniform classes ACC, TC^0, and NC^1.

6 Generalized Quantifiers

We will now formally define the new quantifiers with which we will augment the first-order system in order to express languages in larger complexity classes. We will begin with several

examples, each of which will correspond to one of the new gate types introduced in Section 4. We will then give a general definition. Later, in our main theorem, we will show that each such augmented first-order system can express exactly those languages in the corresponding $DLOGTIME$-uniform circuit complexity class.

We begin with *modular counting quantifiers* $Q_{m,a}$ for each positive integer m and each integer a with $0 \leq a < m$. Given a formula $\varphi(x)$ with one free variable x, we consider the truth values of $\varphi(x)$ as x ranges over the positions in the input. The sentence $(Q_{m,a}x)\varphi(x)$ is defined to be true exactly if the number of positions x making $\varphi(x)$ true is equal to a modulo m. For example, the formula $(Q_{2,1}x)C_1(x)$, over the alphabet $\{0,1\}$ represents the parity language of [FSS84]. We define the class FOC (first-order with counters) to be those languages expressible by first-order formulas containing ordinary quantifiers and modular counting quantifiers. From the above example, we can see that FOC contains languages not in AC^0 and thus strictly contains FO. Clearly a first-order formula with modular counting quantifiers may be evaluated on a particular input by an ACC circuit, as a quantifier $Q_{m,a}$ can be simulated by a gate computing the function $MOD(m,a)$. Thus $FOC \subseteq ACC$.

Next we define the *majority quantifier* M, which captures the notion of threshold computation. Again let $\varphi(x)$ be a formula with one free variable x and consider the truth values of $\varphi(x)$ as x ranges through all the input positions. The sentence $(Mx)\varphi(x)$ is defined to be true exactly if $\varphi(x)$ is true for more than half of the possible x. We also define quantification over pairs of variables, e.g., $(Mxy)\varphi(x,y)$, for φ a formula with two free variables, is true iff $\varphi(x,y)$ is true for a majority of pairs $\langle x,y\rangle$. (We will show below in Proposition 11.3 that this quantifier may be simulated by the ordinary majority quantifier and the BIT predicate. We have not been able to express the majority-of-pairs quantifier using the one-variable majority quantifier in the absence of BIT, and we conjecture that this is impossible.) In Section 11 below we shall see that this quantifier can be used to express a wide variety of predicates. As each use of the majority quantifier can be simulated by a majority gate, the languages expressible by first-order formulas with majority quantifiers (the class FOM) form a subset of TC^0.

Each of these types of quantifiers can be thought of as performing a computation on the values of $\varphi(x)$ for the different x. In the case of an ordinary universal quantifier these values are multiplied to give the truth value of the quantified formula $(\forall x)\varphi(x)$. In the case of an ordinary existential quantifier these values are added in the two-element Boolean algebra. In the case of the modular counting quantifiers the values are added modulo m and the result is compared with some specified value a. Finally, in the case of the majority quantifiers the values are added as integers and compared with some specified value.

Our last quantifier type is a generalization of the modular counting quantifiers, the *group quantifiers*. There is a natural order on the positions x in the input, so that the values of a formula $\varphi(x)$ provide an ordered sequence as x ranges through the positions. There is no reason why we cannot think of applying a noncommutative operation on this sequence. In particular, the operation of multiplication in a nonsolvable group appears to have particular computational significance. Can we capture this operation in the first-order setting by a

new quantifier type?

To do so, we must have "truth values" with more than two possible values, as follows. Fix a finite group G and a mapping from $\{0,1\}^k$ onto G for some fixed integer k. Let $\langle \varphi_1(x), \ldots, \varphi_k(x) \rangle$ be a vector of first-order formulas with a single common free variable x. For each x, let $g(x)$ be the element of G denoted by the vector of truth values $\langle \varphi_1(x), \ldots, \varphi_k(x) \rangle$. For each element g of G, and each input of length n, we define the sentence $(\Gamma^{G,g}x)\langle \varphi_1(x), \ldots, \varphi_k(x) \rangle$ to be true iff the element of G obtained by multiplying $g(1)g(2)\ldots g(n)$ is g. This idea allows us to immediately define *monoid quantifiers* for any finite monoid M and map from $\{0,1\}^k$ onto M, but we will use only group quantifiers in this paper.

We are now ready to define our generalized quantifiers. Though any given augmented first-order system will contain only finitely many such quantifiers, they can be defined for any function meeting a certain technical condition. Let k and ℓ be any fixed integers, and let $f = \{f_1, f_2, \ldots\}$ be a family of functions where f_n is from $\{0,1\}^{\{1,\ldots,k\} \times \{1,\ldots,n\}^\ell}$ to $\{0,1\}$. We say that the family f is *monoidal* if it is derived in the following way from the multiplication operation of a single (possibly infinite) monoid M. First, there must be a map from $\{0,1\}^k$ to M. The input to f_n is interpreted as a sequence of n^ℓ k-tuples of bits whose images in M are multiplied out in lexicographic order. The value of f_n depends only on the element of M which is the result of this multiplication.

For example, the majority quantifier is defined in terms of a function f which inputs a sequence of n bits and returns 1 iff there are at least as many ones as zeroes in the sequence As the inputs are single bits and we operate on n^1 of them, we have $k = \ell = 1$ in this case. The value of f can be determined from the product of the elements of the sequence, computed in a particular infinite monoid. Let $N \times N$ be the monoid of pairs of natural numbers under componentwise addition, and identify the input symbols 0 and 1 with the elements $\langle 1,0 \rangle$ and $\langle 0,1 \rangle$ of $N \times N$ respectively. The product of the elements of the input sequence is then $\langle i,j \rangle$, where the sequence contains i zeroes and j ones. The value of f is 1 exactly if $i \leq j$. Thus the majority gate function, like all the gate functions we have used so far, is monoidal.

Given a monoidal f, we define a quantifier Q_f which will bind ℓ different variables and operate on a k-tuple of formulas. Given formulas $\varphi_1(\mathbf{x}), \ldots, \varphi_k(\mathbf{x})$ with a vector $\mathbf{x}$ of common free variables $x_1, \ldots, x_\ell$, we can define a sentence $(Q_f x_1, \ldots, x_\ell)\langle \varphi_1(\mathbf{x}), \ldots, \varphi_k(\mathbf{x}) \rangle$. The value of this sentence is f applied to all the n^ℓ vectors of truth values $\langle \varphi_1(\mathbf{a}), \ldots, \varphi_k(\mathbf{a}) \rangle$ for each ℓ-tuple $\mathbf{a} = \langle a_1, \ldots, a_\ell \rangle$ with $1 \leq a_j \leq n$ for each $1 \leq j \leq \ell$.

As one more example, we can now define a quantifier which determines the transitive closure of a width-5 directed graph (an NC^1-complete problem, as described in the next section (or see [Ba89])). Our graph will be an array of n^ℓ columns of five nodes each, with directed edges from nodes in column y going only to column $y+1$. We will denote such graphs by a 25-tuple of formulas $\varphi_{i,j}(x_1, \ldots, x_\ell)$ for $1 \leq i,j \leq 5$. For a particular i, j, and ℓ-tuple $\langle x_1, \ldots, x_\ell \rangle$, $\varphi_{i,j}(x_1, \ldots, x_\ell)$ is true is there is an edge from node i in column y

to node j in column $y+1$, where $y = \sum_{z=1}^{\ell}(x_z - 1)n^{z-1}$. The function $\mathrm{W_5TC}_{i,j}$ for each $1 \leq i,j \leq 5$ inputs such a graph and outputs whether there is a directed path from node i in column 0 to node j in column $n^\ell - 1$.

Note that each function $\mathrm{W_5TC}_{i,j}$ derives from a binary operation on columns which is associative and has an identity, and is thus monoidal. We can thus apply the formalism above (with $k = 25$ and ℓ as given), and define quantifiers $Q_{\mathrm{W_5TC}_{i,j}}$. If the formulas $\varphi_{i,j}$ represent a graph, the sentence

$$(Q_{\mathrm{W_5TC}_{i,j}} x_1, \ldots, x_l)\langle\varphi_{1,1}(x_1, \ldots, x_\ell), \ldots, \varphi_{5,5}(x_1, \ldots, x_\ell)\rangle$$

is thus true iff there is a path from node i in column 0 to node j in column $n^\ell - 1$ in that graph.

7 Log-time Turing machines

We define a *log-time Turing machine* to have a read-only input tape of length n, a constant number of read-write work tapes of total length $O(\log n)$, and a read-write input address tape of length $\log n$. On a given time step the machine has access to the bit of the input tape denoted by the contents of the address tape (or to the fact that there is no such bit, if the address tape holds too large a number). We will assume (without loss of generality) that the machine always takes the same amount of time on inputs of a given length (this is because some of the work tape can always be used as a clock). The following lemma summarizes some useful capabilities of such a machine.

Lemma 7.1 *A deterministic log-time Turing machine can (a) determine the length of its input, (b) add and subtract numbers of $O(\log n)$ bits, (c) determine the logarithm of a binary number of $O(\log n)$ bits, and (d) decode a simple pairing function on strings of length $O(n)$.*

Proof: For (a), use binary search with the aid of the "input out of range" response (this idea is described in [Bu87] and credited there to Dowd). For (b), put the numbers on work tapes and simulate the finite automaton which adds or subtracts -- this requires $O(\log n)$ time as only one pass over the numbers is needed. For (c), make a sweep over the number while operating a binary counter on another work tape. The counter takes time linear in the number counted. For (d), we may encode $\langle x, y\rangle$ by first listing the lengths of x and y in binary, then x, then y. Addresses of bits within x or y may then be calculated by addition. The format for giving the lengths must be parsable in $O(\log n)$ time. One scheme would be to list bits 0 and 1 of the lengths by 00 and 01 respectively, and use the pair 11 as a separator. ∎

We define an *alternating log-time machine* as an extension of this model in the usual way (see, e.g., [CKS81]), with certain further assumptions. As with the deterministic machine,

we will use a clock to insure that the running time depends only on the input length. We will assume that the machine alternates between existential and universal states and that it has exactly two options from each such state. It records the sequence of choices on one of its worktapes, so that every configuration of the machine is reached by a unique computation path. Finally, we will assume that the alternating machine queries its input only once in a computation, in its last step. An alternating machine with this restriction can simulate an ordinary alternating machine (which queries the input on every step) at a potential cost of doubling the time taken. At each step of the ordinary machine, the restricted machine guesses the value of the input to be read and universally branches to two computation paths — one which continues the computation assuming that the bit is correct and one which waits for the last step of the computation and then checks the bit. Only one bit is queried on each computation path. Each final state of the restricted machine is of the form "accept", "reject", or "accept iff bit x_i (or $\overline{x_i}$) has value 1". We define $DLOGTIME$ and $ALOGTIME$ as the classes of languages recognizable in deterministic and alternating log-time Turing machines, respectively.

Following Buss [Bu87], we define $DLOGTIME$-uniform NC^1 to be the class of languages recognized by families of Boolean formulas, with depth $O(\log n)$, for which a deterministic log-time Turing machine can decide the *formula language* $\{\langle c, i, y\rangle : |y| = n$ and the i^{th} character of the n^{th} formula is $c\}$. The question immediately arises whether strengthening the uniformity restriction has changed the class NC^1. It has not.

Lemma 7.2 *The class $DLOGTIME$-uniform NC^1 equals $ALOGTIME$, or NC^1-uniform NC^1.*

Proof: Buss [Bu87] shows that the definition of $ALOGTIME$-uniform NC^1 in terms of the formula language is equivalent to Ruzzo's original definition [Ru81] in terms of the extended connection language for circuits. This and Ruzzo's result show that $DLOGTIME$-uniform NC^1 is a subset of $ALOGTIME$, so it remains for us only to show that an $ALOGTIME$ machine may be simulated by a $DLOGTIME$-uniform formula family.

We name each configuration of the alternating Turing machine by the sequence of choices leading to it (recall that this choice sequence is recorded on one of the machine's work tapes). We construct a circuit family to simulate the alternating machine in the standard way. We will then show how the circuit for each n (which is a tree) can be denoted by a $DLOGTIME$-uniform formula. A similar and independent argument is used for the same purpose in [BCGR89]. The body of the circuit is easy to define – it has OR gates for the existential choices and AND gates for the universal choices of the $ALOGTIME$ machine, in a full binary tree with alternating AND and OR rows. Note that this circuit is a *balanced* tree, i.e., that all paths from the top to the bottom have the same length because the alternating machine always runs for the same time, which we will call t. The only difficulty comes at the leaves of the tree, where we must place the input variable corresponding to the input position queried by the machine in the case when the sequence of choices, corresponding to that leaf, is made.

Formally, we will define a formula f_σ for every binary string σ of length $\leq t$, such that f_ϵ (where ϵ is the empty string) is the desired formula denoting the whole circuit. Once we have done this, we will explain how to insert spaces into f_ϵ in such a way that it becomes $DLOGTIME$ uniform. First we define two families of strings: $op(\sigma)$ for every σ with $|\sigma| < t$, and $query(\sigma)$ for every σ with $|\sigma| = t$. The string $op(\sigma)$ will be the single character $\vee$ or $\wedge$ corresponding to the type of state (existential or universal) of M after carrying out the choice sequence corresponding to σ (by one of our assumptions, this depends only on the parity of $|\sigma|$, but it could in any case be calculated in $DLOGTIME$ by simulating M). The string $query(\sigma)$ will be x_i or $\neg(x_i)$, corresponding to the input query made by M at the end of a run with choice sequence σ. This can also be calculated in $DLOGTIME$ by simulating M -- note that both $op(\sigma)$ and $query(\sigma)$ are independent of the input. Now we can define f_σ recursively. The base case is $f_\sigma = query(\sigma)$ for $|\sigma| = t$, and the general case for $|\sigma| < t$ is $f_\sigma = (f_{\sigma 0} op(\sigma) f_{\sigma 1})$.

We will lay out f_ϵ in $2^{t+1} - 1$ blocks of equal size. The block size will be the least power of two exceeding both $2t - 1$ and $(\log n) + 2$, which is still $O(\log n)$. The block numbers will be binary integers of length $t + 1$, possibly with leading zeroes. Each block will be padded on the right with spaces. Blocks of the form $\sigma 1$ will contain the string $query(\sigma)$. Blocks of the form $\sigma 0$ contain the operators and the parentheses, to wit:

- if $\sigma = 0^t$, then block $\sigma 0 = (^t$.
- if $\sigma = \tau 10^j$, then block $\sigma 0 =)^j op(\tau)(^j$.
- if $\sigma = 1^t$, then block $\sigma 0 =)^t$.

The reader may verify that the ordered concatenation of these blocks, ignoring spaces, is the string f_ϵ. The given block size suffices to contain all blocks, as each $query(\sigma)$ has length $\lceil \log n \rceil + 2$ and the longest of the other blocks, block 10^t, has length $2t - 1$.

It remains to show that a $DLOGTIME$ Turing machine, on input n and i, can calculate the i^{th} character of f_ϵ. As shown in Lemma 7.1, it can calculate the block size and its logarithm, and thus determine which character of which block is the i^{th} overall. It can then simulate M with the appropriate choice sequence to determine what that block is, and explicitly find the correct character as the blocks are of size $O(\log n)$. ∎

With this new notion of uniformity we can reexamine the characterizations of NC^1 in terms of constant-width branching programs [Ba89] or, equivalently, programs over finite monoids [BT88] (the relationship between these various models was discussed above). Here we will paraphrase Barrington's main theorem as follows:

Theorem 7.3 *[Ba89] The problems of multiplying together a sequence of elements of the permutation group S_5, and of finding the transitive closure of a width-5 graph, are complete for NC^1 under AC^0 reductions. This is true in both the non-uniform and $ALOGTIME$-uniform settings.* ∎

We now show that the this theorem also holds in this new uniformity setting. We adopt Buss' definition of $DLOGTIME$ reductions [Bu87]: A function f many-one reducing a language A to a language B is said to be a $DLOGTIME$ reduction if f increases the length of strings only polynomially and the predicate $A_f(c, i, z)$, meaning "the i^{th} symbol of $f(z)$ is c", is recognized by some $DLOGTIME$ Turing machine.

Proposition 7.4 *These two problems remain complete for $DLOGTIME$-uniform NC^1 (i.e., for $ALOGTIME$) under $DLOGTIME$ reductions.*

Proof: This is very similar to the proof of Lemma 7.2 above. Given an arbitrary alternating log-time Turing machine, there is a canonical balanced $DLOGTIME$-uniform log-depth formula simulating it, as shown above. Further, there is a canonical branching program obtained from that formula by the method of [Ba89]. We will show that the function taking an $ALOGTIME$ machine to a description of the branching program for that machine is a $DLOGTIME$ reduction. For any particular input, a solution to either of the two given problems can be used to evaluate this branching program, and thus simulate the machine, on that input.

It suffices to show how a $DLOGTIME$ machine can obtain the i^{th} instruction of the branching program given i in binary. We need first to determine which input variable is to be referenced. This is the variable queried by the alternating machine after a particular choice sequence, in fact (examining the method of [Ba89]) that given by the odd-numbered bits of the binary encoding of i (viewed as a string of $2t$ bits, possibly with leading zeroes). The $DLOGTIME$ machine can recover these bits and simulate the $ALOGTIME$ machine with the resulting choice sequence. We must then determine which group elements the i^{th} instruction is to output for each of the two possible values of this input variable. This can be determined by tracing the t iterations of the [Ba89] construction leading to the i^{th} instruction, which can be done by a finite-state process running left to right over the bits of i. ∎

This can be interpreted as a simulation of alternating log-time Turing machines by $DLOGTIME$-uniform branching program families (analogous to the $ALOGTIME$-uniform families of [Ba89]), or $DLOGTIME$-uniform programs over the monoid S_5, as in [BT88].

Just as above we expanded the circuit model by adding new gates, we can expand the log-time Turing machine model by adding new types of states generalizing the idea of alternation. To match circuits of unbounded fan-in, we must allow the existence of a number of normal deterministic states between the special states, and count depth of special states. Examples are:

- Normal alternating machines of constant alternation depth. This yields the important *alternating log-time hierarchy*, and the class LH of languages accepted by constant-depth alternating log-time machines.

- States whose acceptance depends on the number of accepting successor paths modulo some constant.
- States whose acceptance depends on whether a majority of the successor paths are accepting, as defined by Parberry and Schnitger [PS88].
- States which are analogues of the group-multiplying circuit gates defined in Section 4 above.

8 Equivalence of FO and the Log-time Hierarchy

Our main result (Theorem 9.1) depends primarily upon the fact that first-order formulas are powerful enough to express the notion of acceptance by a $DLOGTIME$ Turing machine. In fact, we shall soon see that a language can be so expressed iff it is in LH, the alternating log-time hierarchy.

Proposition 8.1 $DLOGTIME \subsetneq FO$.

Proof: Let T be a DLOGTIME machine with k work tapes. We must write a first-order sentence φ such that for all input strings $\mathcal{A}$:

$$T \text{ accepts } \mathcal{A} \quad \Leftrightarrow \quad \mathcal{A} \models \varphi \,.$$

The sentence φ will begin with existential quantifiers, $\varphi \equiv (\exists x_1 \ldots x_c)\psi(\mathbf{x})$. The vector of variables $\mathbf{x} \quad \langle x_1, \ldots, x_c \rangle$ will code the $O(\log n)$ steps of T's computation including, for each time step t, the values $q_t, w_{1,t}, \ldots, w_{k,t}, d_{1,t}, \ldots, d_{k,t}, I_t$ representing T's state, the symbol it writes on each tape, the direction each head moves, and the value of the input being scanned by the index-tape controlled input head at time t, respectively. (It is important to remember that each variable x_i is a $\lfloor \log n \rfloor + 1$ bit number and that the logical relation BIT allows its individual bits to be specified, so the values $q_t, w_{i,t}, d_{i,t}, I_t$ are available from the variables $\mathbf{x}$.)

The formula ψ must now assert that the information in $\mathbf{x}$ meshes together to form a valid accepting computation of T. To do this we first define the first-order formulas $C(p,t,a)$ and $P(p,t)$ meaning that for the computation determined by $\mathbf{x}$, the contents of cell p at time t is a; and that the appropriate work head is at position p at time t. Here the "position" p encodes also which tape the cell is on. Given C and P, we can write the formula ψ as follows. We must assert that for all t, the input symbol I_t is correct. To do this we say that there exists a variable y equal to the contents of the index tape. (This can be verified using the formula C.) Next we say that I_t is one iff the corresponding input relation $X(y)$ holds. Finally we assert that the next move of T, i.e. $q_{t+1}, w_{1,t+1}, \ldots, w_{k,t+1}, d_{1,t+1}, \ldots, d_{k,t+1}$, follows according to T's finite control from the current state, q_t, input symbol, I_t, and tape symbol, the unique a such that there exists p so that $C(p,t,a)$ and $P(p,t)$ both hold.

Next note that using P we can write C because the contents of cell p at time t is just w_{i,t_1} where t_1 is the most recent time that the appropriate head i was at position p, or the blank symbol if that head is never at P before time t.

Finally observe that to write the relation $P(p,t)$ it suffices to take the sum of $O(\log n)$ values of $d_{t'}$ for $t' < t$. Thus it suffices to prove the following technical result:

Lemma 8.2 *Let $BSUM(x,y)$ be true iff y is equal to the number of ones in the binary representation of x. Then BSUM is first-order expressible.*

Proof: Let $L = \lfloor \log n \rfloor + 1$, and $L_2 = \lfloor \log L \rfloor + 1$. These numbers are available using BIT. For example L is the unique number satisfying,

$$\mathrm{BIT}(L,n) \wedge (\forall x)(x > L \rightarrow \neg \mathrm{BIT}(x,n)) .$$

We express BSUM as follows. We may assume that $L \geq (L_2)^2$ by keeping a table of special cases for $L < 9$. Then we existentially quantify one variable s consisting of L_2 L_2-bit numbers $s_1, \ldots, s_{L_2}$, where each s_{i+1} is the sum of s_i and the number of ones in the binary expansion of x between bits $i \cdot L_2 + 1$ and $(i+1) \cdot L_2$. Thus s_{L_2} is equal to the bit sum of x. For example, see the table below in which $L = 9$, $L_2 = 3$, and x's bit sum of 6 is calculated.

To express the correctness of the sequence of partial sums, s, we need to express the sum of variables, and to express the bit sum of a set of L_2 consecutive bits from x. This latter bit sum can be expressed by the existence of L_2 partial sums, where a partial sum is taken for each of the L_2 bits we are summing. For example, in the table below, to say that bits 7 through 9 of s are correct, we would assert that there are 2 bits on from bits 7 through 9 of x, and that the sum of 4 (bits 4 through 6 of s) and 2 is equal to 6 (bits 7 through 9 of s). To say that there are 2 bits on from bits 7 through 9 of x, we would assert the existence of r in the following table, containing the running sum for each of bits 7, 8, and 9 of x.

	1	2	3	4	5	6	7	8	9
x	1	1	1	0	1	0	1	0	1
s	0	1	1	1	0	0	1	1	0
r	0	0	1	0	0	1	0	1	0

Finally, we express the predicate $PLUS(a,b,c)$ meaning that $a + b = c$. This is just carry look ahead addition. First express the carry into the i^{th} bit of $a + b$ as follows:

$$CARRY(i) \equiv (\exists j < i)[\mathrm{BIT}(j,a) \wedge \mathrm{BIT}(j,b) \wedge (\forall k.j < k < i)\mathrm{BIT}(j,a) \vee \mathrm{BIT}(j,b)]$$

Then with $\oplus$ standing for exclusive or, we can express PLUS,

$$PLUS(a,b,c) \equiv (\forall i)[\mathrm{BIT}(i,c) \leftrightarrow (\mathrm{BIT}(i,a) \oplus \mathrm{BIT}(i,b) \oplus CARRY(i))]$$

Corollary 8.3 $FO = LH$.

Proof: To prove $LH \subseteq FO$, we need only note that an alternating log-time machine may be assumed to write its guesses on a work tape and then deterministically check for acceptance. Since a first-order sentence can just as easily quantify these alternating guesses, it suffices to express a $DLOGTIME$ predicate using Proposition 8.1 above.

The other direction is fairly easy. We have to show that for every first-order sentence,

$$\varphi \equiv (\exists x_1)(\forall x_2)\ldots(Q_k x_k)M(\mathbf{x})$$

there exists an alternating, constant-depth log-time Turing machine T such that for all input strings $\mathcal{A}$,

$$T \text{ accepts } \mathcal{A} \Leftrightarrow \mathcal{A} \models \varphi .$$

Since M is a constant size quantifier-free formula, it is easy to build a $DLOGTIME$ Turing machine which on input $\mathcal{A}$ and with values $a_1, \ldots, a_k$ on its tape, tests whether or not $\mathcal{A} \models M(\mathbf{a})$. (The most complicated part of this is to verify the BIT predicate, which requires counting in binary up to $O(\log n)$ on a work tape as in Lemma 7.1.) Thus using $k-1$ alternations between existential and universal states, a Σ_k log-time machine can guess $a_1, \ldots, a_k$ and then deterministically verify $M(\mathbf{a})$. ∎

9 Proof of Main Theorem

We now restate our main theorem, using the more precise definitions we have developed in sections 4 (DCL-uniform, generalized expressions) and 7 ($DLOGTIME$):

Theorem 9.1 *Let $\mathcal{F}$ be any set of monoidal functions. The following are equivalent definitions of "L is in uniform $AC^0[\mathcal{F}]$" (e.g., AC^0, ACC, TC^0, or NC^1):*

1. *L is first-order definable using $\mathcal{F}$ quantifiers.*
2. *L is recognized by a $DLOGTIME$-DCL-uniform family of constant-depth, polynomial-size circuits with gates for AND, OR, and a finite set of functions in $\mathcal{F}$.*
3. *L is recognized by an FO-DCL-uniform family of such circuits.*
4. *L is recognized by a $DLOGTIME$-uniform family of constant-depth, polynomial-length generalized expressions using AND, OR, and a finite set of functions from $\mathcal{F}$.*
5. *L is recognized by a FO-uniform family of such expressions.*

For NC^1 and above, these definitions also coincide with the earlier notion of NC^1 uniformity [Ru81,Co85].

Proof: $1 \Rightarrow 2$:

Corresponding to any first-order formula of quantifier depth d in prenex form is a canonical constant-depth circuit for each n. A tree of fan-out n and depth d corresponds to the quantifiers, and at each leaf of this tree there is a constant-size constant-depth section. This section calculates the value of the unquantified sentence obtained by taking particular values for each of the quantified variables. It will consist of Boolean operators, input nodes, and constants corresponding to the value of atomic formulas (equality, order, and BIT) on the chosen values of the quantified variables. We need merely show that the nodes of this circuit can be numbered in such a way that DCL queries about it can be answered by a $DLOGTIME$ Turing machine.

This is straightforward and quite similar to our earlier constructions in Section 7. The address of a node will consist of a field of $\lceil \log n \rceil$ bits for each quantifier and a constant-length field for the bottom section. Each node in the n-ary tree section of the circuit can be specified by the sequence of variable choices leading to it. Its node number will have these choices in the fields corresponding to them, and zeroes in the remaining fields. Nodes in the bottom section will have the the choices for all d variables indicated in the first d fields, and a code for the particular node in the last field. In order to answer queries for the direct connection language, the $DLOGTIME$ machine needs to be able to compare fields of length $\lceil \log n \rceil$ (to check connections), to interpret these fields as input variable names (to verify the nodes corresponding to atomic formulas of the form $X(i)$), and to evaluate atomic formulas for given values of the d variables (to verify the values of the constants in the bottom section). This last is possible because a $DLOGTIME$ machine can easily check order, equality, and BIT on numbers in the range from 1 to n.

$2 \Rightarrow 3$: This is immediate from the fact that $DLOGTIME \subseteq FO$.

$3 \Rightarrow 1$: As the circuit is of polynomial size, we can refer to node numbers by tuples of variables. It will suffice to express the predicate $Acc(a)$, meaning "a is the number of an accepting gate (a gate with output 1)" by a first-order formula, because we can then evaluate the circuit by evaluating this predicate on the output gate. To do this we inductively define predicates $Acc_d(a)$, meaning "a is the number of an accepting gate at level d. For level 0, the input to the circuit, $Acc_0(a)$ is just $C_1(x)$ or $C_0(x)$ ANDed with the predicate "a is the number of a input gate for input variable x (or the negation of x)." This last predicate is first-order expressible by hypothesis.

To express $Acc_d(a)$ we will show how to express "a is the number of an accepting f-gate at level d" for a monoidal function f. First we must say "a is the number of an f-gate at level d", which is first-order for any fixed d. Then we need to use a Q_f quantifier to apply f to the sequence of values $Acc_{d-1}(b)$ for all those b which are the numbers of children of a. Here is where we need the assumption that the domain of f contains an identity

element. We write an expression $Acc'_{d-1}(b)$ whose value is $Acc_{d-1}(b)$ if b is a child of a and the identity otherwise. Then our desired predicate is $(Q_f b)Acc'_{d-1}(b)$. Finally, $Acc_d(a)$ is the OR of these predicates over all the functions f used in the circuit.

$1 \Rightarrow 4$: The canonical constant depth circuit which we constructed from a first-order formula above is a tree, and so can be denoted by a general expression, with operators corresponding to the quantifiers. We need to arrange this expression so that the expression language is in $DLOGTIME$. This is easy because we have a space character in our alphabet and allow arbitrary embedded spaces. We simply choose a power of two greater than n and position the terms of the expression so that their position in the tree can be read off from their binary addresses, as in the proof of Lemma 7.2.

$4 \Rightarrow 5$: This is immediate from the fact that $DLOGTIME \subseteq FO$.

$5 \Rightarrow 1$: Here we induct on the structure of the expression just as we inducted on the structure of the circuit above. We define a predicate $Acc_d(a)$ expressing "character number a is the start of an accepting f-term at level d". For fixed d, we can write a first-order formula matching parentheses to depth d, so we can express "character b is the start of a subterm of the term starting at character a", and so forth. Again, we need the identity character in the domain of f so that we can apply f to $Acc_{d-1}(b)$ for exactly those b which are the start of subterms of the term starting at a. ∎

10 Logically Defined Classes With *BIT*

We may now examine the uniform complexity classes given by our examples. First of all, the class FO is also $DLOGTIME$-uniform AC^0 or FO-uniform AC^0. Adding in the modular counting quantifiers, we get a class FOC (first-order plus counters) which is also the $DLOGTIME$-uniform version of the class ACC.

When we add the majority quantifier we get the class FOM (first-order plus majority) or $DLOGTIME$-uniform TC^0. This class contains nearly all of the languages known to be in (uniform) NC^1, such as the many examples, given by Chandra et al., of languages equivalent to majority under AC^0 reductions [CSV84]. (The constructions in that paper can all be made uniform using the methods which we will develop in the next section.) The two notable exceptions are the word problem for a non-solvable group [Ba89] and the Boolean formula value problem [Bu87]. These two problems (and several others directly related to them) are complete for NC^1 under uniform AC^0 reductions, and are thus not in TC^0 unless $TC^0 = NC^1$. We should mention also that the several problems only known to be in P-uniform NC^1, such as those of Beame et al. [BCH84] and of Reif [Re87], are not known to be in this new class.

Finally, we consider the effect of the group quantifiers and the width-5 transitive closure operator. Group quantifiers for solvable groups (in fact, monoid quantifiers for solvable monoids) can be simulated by iterated modular counting quantifiers [STT88]. However, by

Theorem 9.1 and Proposition 7.4 (our $DLOGTIME$-uniform version of Barrington's theorem [Ba89]), we know that first-order formulas using quantifiers for any single non-solvable group G can express exactly those languages in $DLOGTIME$-uniform NC^1. Furthermore, the same is true of the W_5TC operator. The group quantifiers correspond exactly to circuit gates for G's word problem, and the width-5 closure operator decides whether a particular definable width-5 branching program accepts its input. To summarize, we have:

Corollary 10.1 *First-order logic, with the addition of either the width 5 transitive closure operator or a multiplication quantifier for a non-solvable group, expresses exactly those languages in uniform NC^1.*

Now that we have robust notions of "uniform NC^1" and "uniform AC^0", we can restate Proposition 7.4 as a uniform version of Barrington's Theorem:

Corollary 10.2 *The word problem for S_5 (or for any non-solvable monoid) is complete for uniform NC^1 under uniform AC^0 reductions. Therefore, uniform branching program families of width 5 and polynomial size recognize exactly uniform NC^1.* ∎

11 Logically Defined Classes Without BIT

The basic operations of the first-order logical system include one which is noticeably less natural than the others – the BIT predicate. In fact the system without BIT was explored first, in the course of efforts to classify regular languages according to algebraic properties. Further exploration of this system leads deeper into algebraic automata theory — see, e.g., Eilenberg [Ei76], Lallement [La79], or Pin [Pi76] for background and definitions.

McNaughton and Papert [MP71] proved that in the system without BIT, the languages expressible by first-order formulas are exactly the *aperiodic* or *star-free* regular languages (see Ladner [La77] for a good exposition of this result in more modern terminology). This is a well-studied subclass of the regular languages with a number of characterizations. Here we mention only the closely related result of Chandra et al. [CFL83] that an associative operation on a finite set (a semigroup) can be carried out in AC^0 iff the semigroup is *group-free.*

The modular counting quantifiers described above were actually introduced as an extension of this system as well. Straubing et al. [STT88] prove that with these quantifiers but without BIT one can define exactly the *solvable regular* languages, i.e., those languages recognized by monoids that contain only solvable groups. If $ACC \neq NC^1$, this class of languages is exactly the intersection of ACC with the regular languages [BCST88]. By adding operators which evaluate n modulo a constant, the first-order system without BIT can be modified to give exactly those regular languages in non-uniform AC^0 [BCST88].

Adding majority quantifiers will naturally take us out of the regular languages. But surprisingly, the expressibility class we obtain is a familiar one — the same uniform TC^0 we obtained with BIT. To see this, we first show that we can express first-order arithmetic on variables in this system:

Lemma 11.1 *The following formulas are expressible in FO(w.o. BIT) plus majority of pairs:*

1. *"$(Hx)\varphi(x)$", "$(H^2xy)\varphi(x,y)$", i.e. φ is true for exactly $\lfloor n/2 \rfloor$ x's, resp. $\lfloor n^2/2 \rfloor$ pairs x, y.*
2. *"$y = \sharp x : \varphi(x)$", i.e. y is the exact number of x's such that $\varphi(x)$.*
3. *"$x + y = z$"*
4. *"$x \cdot y = z$"*

Proof: To express $(Hx)\varphi(x)$ we say that φ is not true for the majority of x's, but it becomes true if we add one more x. H^2 is similar.

$$(Hx)\varphi(x) \equiv (\exists y)(Mx)(\varphi(x) \vee x = y) \wedge \neg(Mx)\varphi(x))$$

To express (2) we create a two-variable predicate $\psi(w,z)$ that is true for $w = 1$ and $z < y$, for $w = 2$ and $\varphi(z)$, and for half of the pairs with $w > 2$. Then

$$(y = \sharp x : \varphi(x)) \equiv (H^2wz)(\psi(w,z)) .$$

Similarly, we can create a predicate that compares z with $x + y$ to express (3). We force z values to zero by fixing the $w = 1$ and $w = 2$ columns, x values to one with the $w = 3$ column, y more values to one with the $w = 4$ column, and split the other columns evenly between zeroes and ones. The resulting predicate is exactly evenly divided iff $x + y = z$. The predicate that compares z with $x \cdot y$ for (4) is only slightly more subtle. We make a section of z zeroes and a rectangular section of $x \cdot y$ ones. Note that x and y are both less than $n/2$ and z (except for the cases $x = 1$,$y = 1$, $n = 1, 2$ which can be handled in separate clauses).

∎

It now follows that:

Theorem 11.2 *Even without BIT, First-order Logic plus Majority is equal to uniform TC^0.*

Proof: It suffices to express BIT in FO(w.o. BIT) + M^2. This follows from Lemma 11.1. Note that we can express, "x is a power of 2" by saying that x has no odd divisors except 1. Next we can express, "$z = 2^i$," as, "z is a power of 2" and $(i = \sharp y : (y < x \wedge$ "y is a power of 2"). Finally, we have:

$$\mathrm{BIT}(x,i) \equiv (\exists uw)(w < 2^i \wedge u \text{ is odd} \wedge x = w + u2^i)$$

∎

It is slightly annoying that we needed M^2 rather than just M in Lemma 11.1. As the next proposition shows, this is not necessary in the presence of BIT. We conjecture that it is necessary without BIT.

Proposition 11.3 *The majority-of-pairs quantifier $(M^2xy)\varphi(x,y)$ is expressible in (FO + M), i.e. using the BIT predicate and the majority quantifier.*

Proof: This is true, because in the presence of BIT we can express addition and multiplication on variables even without majority. Thus we can express the following:

1. $F(x,y)\varphi(x) \equiv$ "There are exactly y values of x less than or equal to $\lfloor n/2 \rfloor$ such that $\varphi(x)$ holds."
2. $S(x,y)\varphi(x) \equiv$ "There are exactly y values of x greater than $\lfloor n/2 \rfloor$ such that $\varphi(x)$ holds."
3. $(y = \sharp x : \varphi(x))$
4. $(\langle u,v \rangle = \sharp x : \varphi(x,y)) \equiv$ "There are $n(u-1)+v$ pairs x,y such that $\varphi(x,y)$ holds."

(1) is expressed as follows:

$$F(x,y)\varphi(x) \equiv (Hx)[(x \leq \lfloor n/2 \rfloor \wedge \varphi(x)) \vee (\lfloor n/2 \rfloor < x < n+1-y)]$$

(2) is similar, and then (3) follows by addition of variables. Part (4) will involve some expressibility results which are interesting in their own right. (The proofs are adaptations of known techniques to the first-order setting.) We first define a variable $col(x) = \sharp y : \varphi(x,y)$ for each column of the square array, and then we are faced only with the problem of adding n numbers each of $O(\log n)$ bits, which is a special case of the following result.

Proposition 11.4 *The sum of a polynomial number of polynomial-length binary integers (and hence also multiplication of polynomial-length binary integers) can be expressed in FO + M + BIT.*

Proof: This uses a technique due to Chandra, Stockmeyer, and Vishkin [CSV84]. Using the $\sharp$ operator, we find the sum of the units digits, twos digits, fours digits, etc., of the summands. These sums are each a number of $O(\log n)$ bits, and the sum of them (when each is padded on the right with an appropriate number of zeroes) is our desired sum. But these sums can be arranged into $O(\log n)$ numbers of polynomial length, whose sum is the desired sum. It thus suffices to prove the following.

Lemma 11.5 *it add of log n The sum of $O(\log n)$ polynomial-length binary integers (and hence, among other things, multiplication of binary numbers of length $O(\log n)$) is expressible in $FO + BIT$.*

Proof: We use the technique above to reduce the $O(\log n)$ numbers to $O(\log \log n)$ numbers, this time using the $BSUM$ predicate of Lemma 8.2 instead of the $\sharp$ operator and so remaining within $FO + BIT$. We can imagine this process being carried out again and again, reducing the number of summands from $\log \log n$ to $\log \log \log n$, $\log \log \log \log n$, and so forth until it becomes constant and we can finish by addition of variables. In this imagined computation, the part needed to calculate a single bit of the answer consists of less than $\log n$ bits. We can guess a variable which codes up this part of the calculation, using appropriate coding tricks, and verify that each bit of it is correct.

To prove the special case of this Lemma (numbers of length $O(\log n)$) used in Proposition 11.3 and in multiplication of $O(\log n)$-bit numbers, it suffices to use a simpler technique suggested by Sam Buss. He notes that Lipton [Li78] has shown how to multiply binary integers with an alternating Turing machine using a constant number of alternations and time linear in the length of the product. If the product is $O(\log n)$ bits, then, this computation is in LH and thus in FO by Corollary 8.3. Lipton's technique of carrying out an iterated addition modulo all small numbers can easily be adapted to add $O(\log \log n)$ numbers each of length $(\log n)$, which will finish the process after one step of the reduction technique used above. ∎

∎

Clearly (4) gives us M^2. ∎

We now consider the final question about the system without BIT: What are the consequences of adding the group quantifiers or the W_5TC operator? In the case with BIT each gave us all of NC^1 because the construction of Barrington [Ba89] could be carried out. Here, since these operators each can be simulated by a finite-state machine, it is not surprising that all the languages definable in this way are regular (see below). A significant question, however, is whether we can get all regular languages in this way.

In the next section, we will use the structure theory of finite monoids to show that any regular language can be expressed using the right group quantifiers (this will be a special case of Theorem 12.1). Similarly one can show that no non-regular languages are obtained.

One way to see this second fact is to use another expressibility result — that of Büchi [Bü60] on monadic second-order quantifiers (see also [La77]). This result is that sentences with such quantifiers in our system without BIT can express exactly the regular languages. Defining a translation from group quantifiers to weak second-order quantifiers is fairly easy, and gives us the other half of:

Theorem 11.6 *A language can be expressed by a first-order formula with group quantifiers iff it is regular.* ∎

12 Expressing Regular Languages

We can in fact make a much more precise statement about the regular languages expressible with group quantifiers for a particular set of groups. To do this we will need a number of algebraic definitions (see, e.g., [Ei76], [Pi86], [La79] for more background). We have already defined monoids and groups, and we will assume the basic vocabulary of abstract algebra. A monoid M *divides* another monoid N if it is the image of a submonoid of M under a homomorphism. A *variety* of finite monoids (also called a *pseudovariety*) is a family of finite monoids closed under division and direct product. The *wreath product* M wr H of two monoids M and H is the set of pairs (f, h) with f a function from H to M (not necessarily a homomorphism) and h an element of H. This set is viewed as a monoid under the multiplication:

$$(f_1, h_1)(f_2, h_2) = (f, h_1 h_2)$$

where

$$f(h) = f_1(h) f_2(h h_1)$$

If $\mathcal{G}$ is any family of groups, we define the *Jordan-Hölder closure* $[\mathcal{G}]$ to be the closure of $\mathcal{G}$ under wreath product and division. $[\mathcal{G}]$ consists of all groups each of whose composition factors divides a group in $\mathcal{G}$. A monoid is *aperiodic* if every subset which is a group has one element. The variety $\mathcal{A}$ of aperiodic monoids is closed under wreath product, as is the variety of all groups. We define the *Krohn-Rhodes closure* $[\mathcal{G}, \mathcal{A}]$ of a family of groups $\mathcal{G}$ to be the closure of $\mathcal{G}$ and $\mathcal{A}$ (the aperiodics) under wreath product and division. By the Krohn-Rhodes theorem [KRT68], the monoids in $[\mathcal{G}, \mathcal{A}]$ can be characterized in terms of the simple groups which divide them — a monoid is a member iff each such simple group divides a group in $\mathcal{G}$. For example, the *solvable monoids* are the Krohn-Rhodes closure of the cyclic groups (or, in fact, of the abelian or solvable groups).

We say that a language $L \subseteq A^*$ is *recognized* by a monoid M if there is a homomorphism η from A^* (as a monoid under concatenation) to M such that L is the inverse image under η of a subset of M. If L is regular it has a unique *syntactic monoid*, which divides all monoids that recognize L. In this context, recognition by a finite state machine is viewed

as recognition by the monoid of transformations of the machine's states. We are now ready to show the relationship between this recognizability and logical expressability. Recall that we are now expressing properties of strings from some finite alphabet A, using atomic predicates $C_a(i)$ meaning "the i^{th} input is an a".

Theorem 12.1 *Let $\mathcal{G}$ be a family of groups. A language can be expressed using quantifiers for groups in $\mathcal{G}$ and ordinary quantifiers iff it is regular and it is recognized by a monoid in $[\mathcal{G}, \mathcal{A}]$. It can be expressed using only quantifiers for groups in $\mathcal{G}$ iff it is recognized by a group in $[\mathcal{G}]$.*

Proof: This is an extension of [STT88], where the groups in $\mathcal{G}$ were restricted to be cyclic. We indicate here where changes must be made in this proof to accomodate the group quantifiers. In each part of the proof, the second statement of the theorem (about just the group quantifiers) follows from the proof in the general case.

For the first direction, we must show that if L is recognized by a monoid in $[\mathcal{G}, \mathcal{A}]$ then it is expressible with $\mathcal{G}$ quantifiers. L must be recognized by some wreath product of groups in $\mathcal{G}$ and aperiodics – we will use induction on the length of this product.

Fact 12.2 *[St79, Thm 1.4 and Prop. 2.4] If L is recognized by A wr M with A aperiodic, then L can be obtained from languages recognized by M by repeated use of Boolean operations and letter concatenation (the latter takes L and L' to LaL' for any letter a).* ∎

With ordinary quantifiers and Boolean operators, we can express these two operations, so that if all languages recognized by M are expressible then so are all languages recognized by A wr M [Th82, STT88]. It remains to deal with the languages recognized by G wr M for $G \in \mathcal{G}$ by expressing them in terms of group quantifiers, Boolean operations, and expressions for languages recognized by M.

Let L be recognized by G wr M. Without loss of generality we may assume that a word w is in L iff $\varphi(w) = (f^*, m^*)$ for some homomorphism φ from A^* to G wr M, some f^* from M to G, and some m^* in M. This is because any such L may be written as a finite union of such languages. For each input letter a_i, define f_i and m_i such that $\varphi(a_i) = (f_i, m_i)$. Then, by the definition of the wreath product, $\varphi(a_1 \ldots a_r)$ is given by $(f, m_1 \ldots m_r)$ for a particular function f. This function f is defined on an arbitrary element m_0 of M by:

$$f(m_0) = f_1(m_0) f_2(m_0 m_1) \ldots f_r(m_0 m_1 \ldots m_{r-1})$$

The set of words w such that $\mu(w) = m^*$ is recognizable by M and thus expressible by hypothesis. It remains to give a formula to express whether $f = f^*$.

We first build a formula $\eta_{m,a}(x)$ for each $m \in M$ and $a \in A$ denoting "the letter in position x is a and $m_1 \ldots m_r$ m" (where, again, $\varphi(a_i)$ (f_i, m_i)). This construction

is identical to that of [STT88]. Now for each $m_0 \in M$, $f(m_0)$ is calculated by multiplying together a sequence of group elements as described above. If we call these elements $g_{m_0}(1), \ldots, g_{m_0}(n)$, they can all be expressed by a single formula-vector $g_{m_0}(x)$ with free variable x. The group element $g_{m_0}(x)$ is given by $f_x(m_0 m)$ for the unique m such that $\eta_{m,a}(x)$ is true. Once we have $g_{m_0}(x)$, the predicate "$f = f^*$" is expressed by the AND for all $m_0 \in M$ of

$$(\Gamma^{G, f^*(m_0)} x) g_{m_0}(x).$$

For the other direction, we must show that the language expressed by any formula involving group quantifiers for groups in $\mathcal{G}$ and ordinary quantifiers can be recognized by a wreath product of groups in $\mathcal{G}$ and aperiodics. As in [STT88], we define the quantifier type of a formula to be a sequence $(u_1, \ldots, u_s)$ where each u_i is a group in $\mathcal{G}$ or the symbol $\star$. The quantifier type gives the order of the quantifiers in the formula and whether these are group or ordinary ($\star$) quantifiers. We prove the recognizability of expressed languages by induction on the length of the quantifier type.

Again as in [STT88], for any sentence φ we define formulas $\varphi[, x]$ and $\varphi[x,]$, each with one free variable, denoting respectively "the initial segment of the input ending at position $x - 1$ satisfies φ" and "the final segment of the input beginning at position $x + 1$ satisfies φ". These formulas have the same quantifier type as φ. The following lemma may then be proved in an identical manner to the corresponding lemma of [STT88]:

Lemma 12.3 *Let $\varphi(x)$ be a formula of quantifier type π with one free variable. Then there exist sentences α_i, β_i for $1 \leq i \leq r$ of quantifier type π, and there exist $a_1, \ldots, a_r \in A$, such that*

$$\varphi(x) \leftrightarrow \bigvee_{i=1}^{r} (\alpha_i[, x] \wedge \beta_i[x,] \wedge C_{a_i}(x))$$

∎

The only two properties of the group quantifiers used in this proof are (the obvious):

- There are only finitely many inequivalent formulas of a given quantifier type.
- Given any formula-vector $g(x)$ and an input, there is exactly one g such that $(\Gamma^{G,g} x) g(x)$ is true.

We now proceed by induction on the length $|\pi|$ of π, and the case of adding ordinary quantifiers is already handled in [STT88]. It is useful to consider the case $|\pi| = 1$ separately. Here we have a formula $(\Gamma^{G,g} x) g(x)$ where $g(x)$ is made up of Boolean combinations of atomic formulas $C_a(x)$, and thus depends only on the x^{th} input letter. We thus have a map ψ from A to G where $\psi(a)$ is the value of $g(x)$ when $C_a(x)$ is true. We can extend ψ to be

a homomorphism from A^* to G in the obvious way. Then the formula is satisfied by w iff $\psi(w) = g$, so that it is clear that the language expressed by the formula is recognized by G.

To do the inductive step, we need two facts from the general algebraic theory of automata. The first is a generalization of the Schützenberger product of monoids, described in section IX.2 of [Ei76], and requires some preliminary definitions, from section V.9 of [Ei76].

Let A, B, and C be monoids. A *left action* of C on B is a map which assigns an element cb of B to every $c \in C$ and $b \in B$ satisfying a few natural axioms ($1_c b = b, (cc')b = c(c'b), (cb)b' = c(bb')$). Similarly, a *right action* of A on B assigns a $ba \in B$ to every $b \in B$ and $a \in A$, satisfying similar axioms. If these actions commute with each other (i.e., $c(ba) = (cb)a$ so we can write cba), we define a *triple product* (A, B, C) as follows (different actions will in general give rise to different triple products). As a set, (A, B, C) is the direct product $A \times B \times C$ of the three monoids. It becomes a monoid under the operation defined by:

$$(a, b, c)(a', b', c') = (aa', (ba')(cb'), cc')$$

Below we will use the group $G' = G^{M_1 \times M_2}$, the direct product of $|M_1||M_2|$ copies of the group G indexed by the direct product $M_1 \times M_2$. We will use the natural left action of M_1 on G' given as follows. If f is an element of G' specified by an element $f_{c,d}$ for each $c \in M_1$ and $d \in M_2$, and m is an element of M_1, each component $[mf]_{c,d}$ of mf is given by $f_{mc,d}$. Similarly, a right action of M_2 on G' is given by $[fm]_{c,d} = f_{c,dm}$ for each $m \in M_2$. The reader may verify that in the triple product (M_2, G', M_1) defined using these actions, the product of a string of elements $(a_1, f_1, b_1) \ldots (a_r, f_r, b_r)$ is $(a_1 \ldots a_r, h, b_1 \ldots b_r)$, where $h \in G'$ is given for each $c \in M_1$ and $d \in M_2$ by

$$h_{c,d} = [f_1]_{c,db_2 \ldots b_r} \cdots [f_i]_{a_1 \ldots a_{i-1}c,db_{i+1} \ldots b_r} \cdots [f_r]_{a_1 \ldots a_{r-1}c,d}$$

Fact 12.4 *[Ei76] Let η_1 and η_2 be homomorphisms from A^* to monoids M_1 and M_2, respectively. Let ψ, from $M_1 \times A \times M_2$ to a group G, be any map. Associate to each word $w = a_1 \ldots a_r \in A^*$ an element $\gamma(w)$ of G by*

$$\gamma(w) = \prod_{i=1}^{r} \psi(\eta_1(a_1 \ldots a_{i-1}), a_i, \eta_2(a_{i+1} \ldots a_r)).$$

Then $L = \{w : \gamma(w) = g\}$ is recognized by a triple product (M_2, G', M_1), as defined above, where G' is the group $G^{M_1 \times M_2}$.

Proof: The homomorphism ζ taking an element a of A to $(\eta_2(a), h, \eta_1(a))$, where $h(c, d) = \psi(c, a, d)$, recognizes L. The (e_1, e_2) component of the middle term of $\zeta(w)$ is exactly $\gamma(w)$ as defined above. ∎

Fact 12.5 *[Ei76, Prop. V.9.1] Every group that divides a triple product (S_1, T, S_2) is an extension of a group dividing $S_1 \times S_2$ by a group dividing T. In particular, if S_1, T, and S_2 are all members of the variety $[G, A]$ then so is (S_1, T, S_2).* ∎

Now suppose we know that every sentence of quantifier type π (where $|\pi| \geq 1$) defines a language recognized by a monoid in $[\mathcal{G}, \mathcal{A}]$. Consider a sentence $\gamma = (\Gamma^{G,g}x)g(x)$ where $g(x)$ is a vector of formulas each of type π. By Lemma 12.3, each formula $g_i(x)$ in $g(x)$ has an equivalent form

$$\bigvee_{j=1}^{r} (\alpha_{i,j}|, x| \wedge \beta_{i,j}|x, | \wedge Q_{a_{i,j}}(x))$$

where the $\alpha_{i,j}$'s and $\beta_{i,j}$'s are each a sentence of type π. The language expressed by each such sentence is recognized by a monoid in $[\mathcal{G}, \mathcal{A}]$ by the inductive hypothesis. If we take the direct product of the homomorphisms recognizing each such language, we get a homomorphism into the direct product M of all these monoids, which is still in $[\mathcal{G}, \mathcal{A}]$. We can now, with some effort, define a map ψ from $M \times A \times M$ to G so that the language expressed by γ satisfies all the hypotheses of Fact 12.4. Then by Fact 12.5, we know that the language expressed by γ is recognized by a monoid in $[\mathcal{G}, \mathcal{A}]$, and we have completed the proof of Theorem 12.1.

It remains to define $\psi(c, a, d)$ for $c, d \in M$ and $a \in A$. The elements c and d determine truth values of each of the sentences $\alpha_{i,j}$ and $\beta_{i,j}$. If these truth values and the letter a satisfy the disjunction above for some i, we set $\psi(c, a, d) = g_i$. Otherwise we set $\psi(c, a, d) = 1$. This map is well-defined because a particular set of truth values and a particular letter can give rise to only one group element. ∎

One consequence of Theorem 12.1 is that in the absence of the BIT predicate the W_5TC operator is no longer sufficient to express even all regular languages. Informally, this is because the equivalence of width 5 and arbitrary constant width depended on the Barrington construction, which can no longer be carried out under this more restrictive uniformity notion. Furthermore, we can *prove* this assertion from Theorem 12.1, because we can show the W_5TC operator to be equivalent in power to a group quantifier for the group S_5, which is only one of the infinitely many non-abelian simple groups.

13 Directions for Further Research

- We have given robust definitions of uniformity for complexity classes within NC^1. We can speak of uniform circuits, uniform expressions, special kinds of Turing machines, or first-order formulas, and be talking about the same complexity classes. (For the classes explored in Section 11, one could as easily speak of uniform programs over a finite monoid, as in [BT88].) Clearly the next step is to explore these new complexity classes as P and NP have been explored. To take one example, we might ask about an NC^1 analogue of the Berman-Hartmanis conjecture [BH77]: are the two known kinds of languages complete for NC^1 (non-solvable group and formula value) isomorphic by first-order functions? We might hope major questions in this area can be answered more easily, and lead to techniques and intuitions useful in the study of the more powerful complexity classes.

- We now see that the apparently technical addition of the BIT predicate (or the majority operation, which can be used to define it) to the first-order framework has enormous consequences. The two expressibility theories differ provably in the case of group quantifiers, as we have seen. A similar provable difference is known in the case of iterated first-order formulas [Im87b] — NC^1 requires $\Omega(\log n)$ iterations without BIT but $O(\log n/\log\log n)$ with it. (In the former case, the iterations suffice to define BIT itself.) What is so special about BIT — what other predicates would do as well?

- In the presence of BIT multiplication in one nonabelian simple group can be defined in terms of another, in sharp contrast to the pure first-order case. Can BIT and solvable groups define any new (non-solvable) regular languages? If so, then $ACC = NC^1$ in the uniform setting. Can majority and solvable groups define any new regular languages? If so, then $TC^0 = NC^1$ in the uniform setting. Thomas [personal communication] has asked whether even a very weak non-regular predicate, such as "$x = 2y$", can be used to define any new regular languages. A partial answer to this comes from the fact that any language defined using first-order logic and purely numerical predicates such as this must be in non-uniform AC^0. The regular languages in non-uniform AC^0 have been characterized [BCST88], and are all solvable. However, it is still open whether $x = 2y$ might be used to define a language such as the strings of length divisible by 3, which is is non-uniform AC^0 but not in FO. Further questions along these lines are considered in [BCST88].

- Is it necessary in the absence of BIT for the majority quantifiers to be able to range over pairs of variables, and not just variables?

14 Acknowledgements

We would like to thank Sam Buss, Jay Corbett, Richard Ladner, Steven Lindell, Sushant Patnaik, Larry Ruzzo, Wolfgang Thomas, György Turán, and Alan Woods for various helpful discussions. In addition we would like to thank the two anonymous referees for their comments, which have greatly improved the presentation.
