# ABSTRACT

We introduce Graphene, a method and protocol for interactive set reconciliation among peers in blockchains and related distributed systems. Through the novel combination of a Bloom filter and an Invertible Bloom Lookup Table (IBLT), Graphene uses a fraction of the network bandwidth used by deployed work for one- and two-way synchronization. We show that, for this specific problem, Graphene is  $\Omega(n \log n)$  more efficient at reconciling n items than using a Bloom filter at the information theoretic bound. We contribute a fast and implementationindependent algorithm for parameterizing an IBLT so that it is optimally small in size and meets a desired decode rate with arbitrarily high probability. We characterize our performance improvements through analysis, detailed simulation, and deployment results for Bitcoin Cash, a prominent cryptocurrency. Our implementations of Graphene, IBLTs, and our IBLT optimization algorithm are all open-source code.

# <span id="page-0-0"></span>1 INTRODUCTION

Minimizing the network bandwidth required for synchronization among replicas of widely propagated information is a classic need of many distributed systems. Blockchains [\[41,](#page-13-0) [50\]](#page-13-1) and protocols for distributed consensus [\[18,](#page-12-0) [31\]](#page-12-1) are the most recent examples of systems where the performance of network-based synchronization is a critical factor in overall performance. Whether based on proof-of-work [\[30,](#page-12-2) [41\]](#page-13-0), proof-of-stake [\[15,](#page-12-3) [26\]](#page-12-4), or a directed acyclic graph (DAG) [\[33\]](#page-12-5), guarantees that these systems can scale to a large user base rely on assumptions about synchronization.

In all these systems, if the network protocol used for synchronization of newly authored transactions and newly mined blocks of validated transactions among peers is efficient, there are numerous benefits. First, if blocks can be relayed using less network data, then the maximum block size can be increased, which means an increase in the overall number of transactions per second. Second, blocks that can be relayed using less network data propagate more quickly [\[19\]](#page-12-6), thereby increasing consensus among distributed peers and avoiding conflicts called forks. Moreover, systems based on GHOST [\[45\]](#page-13-2), such as Ethereum [\[50\]](#page-13-1), record forks on the

chain forever, resulting in storage bloat. Finally, using less bandwidth to relay a block allows greater participation by peers who are behind limited-bandwidth links and routes (e.g., China's firewall).

Contributions. In this paper, we introduce Graphene, a method and protocol for synchronizing blocks (and mempools) among peers in blockchains and related systems using a fraction of the network bandwidth of related work. For example, for larger blocks, Graphene uses 12% of the bandwidth of existing deployed systems. To do so, we make novel contributions to network-based set reconciliation methods and the application of probabilistic data structures to network protocols. We characterize our performance through analysis, detailed simulation, and open-source deployments. Our contributions include:

- We design a new protocol that solves the problem of determining which elements in a set M stored by a receiver are members of a subset  $N \subseteq M$  chosen by a sender. We apply the solution to relaying a block of  $n = |N|$  transactions to a receiver holding  $m = |M|$  transaction. We use a novel combination of a Bloom filter [\[11\]](#page-12-7) and an Invertible Bloom Lookup Table (IBLT) [\[28\]](#page-12-8). Our approach is smaller than using current deployed solutions [\[17\]](#page-12-9) and previous IBLTbased approximate solutions [\[23\]](#page-12-10). Further, we prove that our solution to this specific problem (where both parties need all transactions in N) is an improvement of  $\Omega(n \log n)$ over using an optimal Bloom filter alone.
- We extend our solution to the more general case where some of the elements of  $N$  are not stored by receiver. Thus, our protocol extension handles the case where a receiver is missing transactions in the sender's block; we are a small fraction of the size of previous work [\[49\]](#page-13-3) at the cost of an additional message. Additionally, we show how Graphene can efficiently identify transactions held by the receiver but not the sender.
- We design and evaluate an efficient algorithm for parameterizing an IBLT so that it is optimally small in size but meets a desired decode rate with arbitrarily high probability and faster execution times. This result is applicable beyond our context to any use of IBLTs.

- We design and evaluate a method for significantly improving the decode rate of an IBLT when two IBLTs are available. This method is also a generally applicable.
- We provide a detailed evaluation using analysis and simulation to quantify performance against existing systems. We also characterize performance of our protocol as a live Bitcoin Cash deployment, and as an Ethereum implementation for historic blocks. We also show that Graphene is more resilient to attack than previous approaches.

We have publicly released our Bitcoin Cash and Ethereum implementations of Graphene [\[6,](#page-12-11) [9\]](#page-12-12), a C++ and Python implementation of IBLTs including code for finding their optimal parameters [\[5\]](#page-12-13), and we have released a public network specification of our basic protocol for standard interoperability [\[7\]](#page-12-14). It has been adopted by blockchain developers in released clients, replacing past approaches [\[3,](#page-12-15) [4\]](#page-12-16). While our focus is on blockchains, any system that requires set reconciliation, such as CRLite [\[32\]](#page-12-17), where a client regularly checks a server for revocations of observed certificates, or synchronizing PGP key servers [\[43\]](#page-13-4), are also potential use cases for Graphene.

This submission extends and improves upon the authors' previous workshop paper [\[2\]](#page-12-18). The contributions of our prior work included only the first bullet above (i.e., Protocol 1 in Section [3.1\)](#page-3-0) and empirical simulations of its performance. All other contributions listed above are new. This work does not raise any ethical issues.

# <span id="page-1-0"></span>2 BACKGROUND AND RELATED WORK

Below, we summarize and contrast related work in networkbased set reconciliation and protocols for block propagation.

# 2.1 Set Reconciliation Data Structures

Set reconciliation protocols allow two peers, each holding a set, to obtain and transmit the union of the two sets. This synchronization goal is distinct from set membership protocols [\[16\]](#page-12-19), which tell us, more simply, if an element is a member of a set. However, data structures that test set membership are useful for set reconciliation. This includes Bloom filters [\[11\]](#page-12-7), a seminal probabilistic data structure with myriad applications [\[13,](#page-12-20) [35,](#page-12-21) [47\]](#page-13-5). Bloom filters encode membership for a set of size  $n$  by inserting the items into a small array of  $\frac{-n \log_2(f)}{\ln(2)}$  bits; this efficiency gain is the result of allowing a false positive rate (FPR)  $f$ .

Invertible Bloom Lookup Tables (IBLTs) [\[28\]](#page-12-8) are a richer probabilistic data structure designed to recover the symmetric difference of two sets of items. Like Bloom filters, items are inserted into an IBLT's array of c cells, which is partitioned into subsets of size  $c/k$ . Each item is inserted once into each of the  $k$  partitions, at indices selected by  $k$  hash functions. Rather than storing only a bit, the cells store the actual item.

Each cell has a count of the number of items inserted and the xor of all items inserted (called a keySum). The following algorithm [\[23\]](#page-12-10) recovers the symmetric difference of two sets. Each set is stored in an IBLT, A and B, respectively, (with equal  $c$  and  $k$  values). For each pairwise cell of  $A$  and  $B$ , the keySums are xor'ed and the counts subtracted, resulting in a third IBLT:  $A \triangle B = C$  that lacks items in the intersection. The cells in C with count  $= 1$  hold an item belonging to only A, and to only B if count  $= -1$ . These items are removed from  $k - 1$  other cells, which decrements their counts and allows for the additional peeling of new items. This process continues until all cells have a count of 0. (We've elided details about a checkSum field for clarity.) If c is too small given the actual symmetric difference, then iterative peeling will eventually fail, resulting in a decode failure, and only part of the symmetric difference will be recovered.

There are many variations on Bloom filters that present different trade-offs, such as more computation for smaller size. Similarly, IBLTs are one of several alternatives. For example, several approaches involve more computation but are smaller in size [\[22,](#page-12-22) [37,](#page-12-23) [51\]](#page-13-6) (see [\[23\]](#page-12-10) for a comparison). We have not investigated how alternatives to IBLTs improve Graphene's size nor how, for example, computational costs differ. Our focus is on IBLTs because they are balanced: minimal computational costs and small size. While miners may have strong computational resources, full nodes and lighter clients in blockchains do not. More importantly, as our deployment results in Section [5.3](#page-9-0) show, Graphene's size is almost flat as block size increases, demonstrating that IBLTs are a good fit for our problem. Finally, some of these solutions are complementary; for example, minsketch [\[51\]](#page-13-6) can be used within the cells of IBLTs to reduce Graphene's size further.

Comparison to Related Work. We provide a novel solution to the problem of set reconciliation, where one-way or mutual synchronization of information is required by two peers. Our results are significantly better than deployed past works that are based on Bloom filters alone [\[49\]](#page-13-3) or IBLTs alone [\[23,](#page-12-10) [28\]](#page-12-8), as we show in Section [5.3.](#page-9-0)

We provide several contributions to IBLTs. In general, if one desires to decode sets of size j from an IBLT, a set of values  $\tau > 0$  and  $k > 2$  must be found that result in  $c = i\tau$ cells (divisible by  $k$ ) such that the probability of decoding is at least  $p$ . We provide an implementation-independent algorithm for finding values  $\tau$  and  $k$  that meet rate  $p$  and result in the smallest value of c.

This is a significant advance over past work. Goodrich and Mitzenmacher [\[28\]](#page-12-8) provide values of  $\tau$  that asymptotically ensure a failure rate that decreases polynomially with j. But these asymptotic results are not optimally small in size for finite  $j$  and do not help us set the value of  $k$  optimally. Using their unreleased implementation, Eppstein et al. [\[23\]](#page-12-10) identify optimal  $\tau$  and k that meet a desired decode rate for a selection of  $j$  values; however, the statistical certainty of this optimality is unclear. In comparison, using our open-source IBLT implementation [\[5\]](#page-12-13), we are able to systematically produce statistically optimal values  $\tau$  and k for a wide range of j values. Our method, based on hypergraphs, is an order of magnitude faster than this previous method [\[23\]](#page-12-10).

We also contribute a novel method for improving the decode rate of IBLTs, which is complementary to related work by Pontarelli et al. [\[42\]](#page-13-7), who have the same goal.

#### 2.2 Block Propagation

Blockchains, distributed ledgers, and related technology require a network protocol for distributing new transactions and new blocks. Almost all make use of a p2p network of peers, often a clique among miners that validate blocks, and a random topology among non-mining full nodes that store the entire chain. New transactions have an ID equal to their cryptographic hash. When a new transaction is received, a peer sends the ID as the contents of an inventory (inv) message to all d neighbors, who request a getdata message if the transaction is new to them. Transactions are stored in a mempool until included in a valid block. Blocks are relayed similarly: an inv is sent to each neighbor (often the header is sent instead to save time), and a getdata requests the block if needed. The root of a Merkle tree [\[36\]](#page-12-24) of all transactions validates an ordered set against the mined block.

The block consists of a header and a set of transactions. These transactions can be relayed by the sender in full, but this wastes bandwidth because they are probably already stored at the receiver. In other words, blocks can be relayed with a compressed encoding, and a number of schemes have been proposed. As stated in Section [1,](#page-0-0) efficient propagation of blocks is critical to achieving consensus, reducing storage bloat, overcoming network firewall bottlenecks, and allowing scaling to a large number of transactions per second.

Transactions that offer low fees to miners are sometimes marked as DoS spam and not propagated by full nodes; yet, they are sometimes included in blocks, regardless. To avoid sending redundant inv messages, peers keep track, on a pertransaction and per-neighbor basis, whether an inv has been exchanged. This log can be used by protocols to send missing transactions to a receiver proactively as the block is relayed.

Comparison to Related Work. Xtreme Thinblocks [\[49\]](#page-13-3) (XThin) is a robust and efficient protocol for relaying blocks, and is deployed in Bitcoin Unlimited (BU) clients. The receiver's getdata message includes a Bloom filter encoding the transaction IDs in her mempool. The sender responds with a list of the block's transaction IDs shortened to 8-bytes

(since the risk of collision is still low), and uses the Bloom filter to also send any transactions that the receiver is missing. XThin's bandwidth increases with the size of the receiver's mempool, which is likely a multiple of the block size. In comparison, Graphene uses significantly lower bandwidth both when the receiver is and is not missing transactions. However, Graphene may use an additional roundtrip time to repair missing transactions.

Compact Blocks [\[17\]](#page-12-9) is a protocol that is deployed in all Bitcoin Core and Bitcoin ABC clients. In this protocol, the receiver's getdata message is a simple request (no Bloom filter is sent). The sender replies with the block's transaction IDs shorted to 6-bytes (as well as the coinbase transaction). If the receiver has missing transactions, she requests repairs with a followup inv message. Hence, the network cost is 6n bytes, which is smaller than XThin's cost of  $\approx \frac{m \log_2(f)}{8ln(2)} + 6n$ ;<br>however when the receiver is missing transactions. Compact however, when the receiver is missing transactions, Compact Blocks has an extra roundtrip time, which may cost more if enough transactions are missing. Graphene is significantly lower in cost than Compact Blocks, as we show in Section [5.3.](#page-9-0)

Recently, Xthinner [\[48\]](#page-13-8) was proposed as a variant of Xthin that employs compression techniques on the list of transactions in a block. Since the author states that Xthinner is not as compact as Graphene, we do not compare against it [\[8\]](#page-12-25).

## 3 THE GRAPHENE PROTOCOL

The primary goal of Graphene is to reduce the amount of network traffic resulting from synchronization of a sender and receiver; we do so in the context of block propagation. To motivate Graphene, consider a protocol that uses a Bloom filter alone to encode a block containing *n* transactions. Assume the receiver has a mempool of  $m$  transactions that are a super set of the block. If we set the FPR of the sender's Bloom filter to  $f = \frac{1}{144(m-n)}$ , then we can expect the filter to falsely include an extra transaction in a relayed block about once include an extra transaction in a relayed block about once every 144 blocks (once a day in Bitcoin). This approach requires  $\frac{-n \log_2(f)}{8 \ln(2)}$  bytes, and it is easy to show that it is smaller than Compact Blocks (6n bytes) when  $m < 71982340 + n$ .

But we can do better: in Graphene, we shrink the size of the Bloom filter by increasing its FPR, and we remove any false positives with an IBLT. The summed size of the two structures is smaller than using either alone. In practice, our technique performs significantly better than Compact Blocks for all but the smallest number of transactions, and we show in Section [5.3](#page-9-0) that it performs better than any Bloom-filteronly approach asymptotically.

We designed two protocols for Graphene, which we define presently. Both protocols use probabilistic data structures that fail with a tunable probability. Throughout our exposition, we use the concept of probabilistic assurance. Specifically, a property  $A$  is said to be held in data structure  $X$ 

<span id="page-3-3"></span>

Figure 1: (Left) The receiver's mempool contains the entire block; Protocol [1:](#page-3-1) Graphene manages this scenario. (Right) The receiver's mempool does not contain the entire block. Protocol [2:](#page-3-2) Graphene Extended manages this scenario.

with  $\beta$ -assurance whenever it is possible to tune X so that A occurs in X with probability at least  $\beta$ .

In Protocol 1, we assume that the receiver's mempool contains all transactions in the block, a typical case due to the aggressive synchronization that blockchains employ. This scenario is illustrated in Fig. [1-](#page-3-3)Left. As we show in Section [5.3,](#page-9-0) mempools are sufficiently synchronized to use only Protocol 1 almost all the time.

In Protocol 2, we do not assume that the receiver's mempool is synchronized, as illustrated in Fig. [1-](#page-3-3)Right, which allows us to apply it to two scenarios: (i) block relaying between unsynchronized peers; and (ii) intermittent mempool synchronization. A receiver may not be synchronized with the sender because of network failures, slow transaction propagation times relative to blocks, or if the block contains unpropagated low-fee transactions erroneously filtered out as spam. Protocol 2 begins when Protocol 1 fails: the receiver requests missing transactions using a second Bloom filter; and the sender transmits any missing transactions, along with a second IBLT to correct mistakes. (Compact Blocks and XThin also handle this scenario but do so with greater network bandwidth.)

#### <span id="page-3-0"></span>3.1 Protocols

Our first protocol is for receivers whose mempool contains all the transactions in the block; see Fig. [1-](#page-3-3)Left.

#### <span id="page-3-1"></span>PROTOCOL 1: Graphene

- 1: Sender: The sender transmits an inv (or blockheader) for a block.
- 2: Receiver: The receiver requests the unknown block, including a count of transactions in her mempool,  $m$ .
- 3: Sender: The sender creates Bloom filter S and IBLT I from the transaction IDs of the block (purple area in Fig. [1-](#page-3-3)Left). The FPR of **S** is  $f_S = \frac{a}{m-n}$ , and the IBLT  $\sum_{m=n}^{n}$  is parameterized such that  $a^*$  items can be recovered, where  $a^*$  > a with  $\beta$ -assurance (outlined in green in Fig. [2\)](#page-4-0). We set a so as to minimize the total size of S and

I. S and I are sent to the receiver along with the block header (if not sent in Step 1).

4: Receiver: The receiver creates a candidate set Z of transaction IDs that pass through S, including false positives (purple and dark blue areas in Fig. [2\)](#page-4-0). The receiver also creates IBLT **I'** from Z. She subtracts  $I \triangle I'$ , which evaluates to the symmetric difference of the two sets [\[23\]](#page-12-10). Based on the result, she adjusts the candidate set, validates the Merkle root in the block header, and the protocol concludes.

In blockchains, the sender knows the transactions for which no inv message has been exchanged with the receiver (e.g., Bitcoin's filterInventoryKnown data structure); those transactions could be sent at Step 3, and in fact our implementation does just that. (N.b., the IBLT stores only 8 bytes of each transaction ID; but full IDs are used for the Bloom filter.)

We use a fast algorithm to select  $a$  such that the total amount of data transmitted over the network is optimally small; see Section [3.3.1.](#page-4-1) The count of false positives from S has an expected mean of  $(m − x)$ f<sub>S</sub> = a, whose variance comes from a Binomial distribution with parameters  $(m - x)$ and  $f_S$ . If higher performance is desired that accounts for this variance, then  $a^*$  should be used to parameterize I instead of a. We derive a<sup>\*</sup> in Section [3.3.1](#page-4-1) via a Chernoff bound.

## 3.2 Graphene Extended

If the receiver does not have all the transactions in the block (Fig[.1-](#page-3-3)Right), IBLT subtraction in Protocol 1 will not decode. In that case, the receiver should continue with the following protocol. Subsequently, we show how this protocol can also be used for intermittent mempool synchronization. Our contribution is not only the design of this efficient protocol, but the derivation of parameters that meet a desired decode rate.

#### <span id="page-3-2"></span>PROTOCOL 2: Graphene Extended

- 1: Receiver: The size of the candidate set is  $|Z| = z$ , where  $z = x + y$ , a sum of x true positives and y false positives (purple and dark blue areas in Fig. [3\)](#page-4-0). Because the values of  $x$  and  $y$  are obfuscated within the sum, the receiver calculates  $x^*$  such that  $x^* \leq x$  with  $\beta$ -assurance (green outline in Fig. [3\)](#page-4-0) She also calculates  $y^*$  such that  $y^* \geq y$  with  $\beta$ -assurance (green outline in Fig. [4\)](#page-4-0).
- 2: Receiver: The receiver creates Bloom filter  $R$  and adds all transaction IDs in  $Z$  to  $R$ . The FPR of the filter is  $f_R = \frac{b}{n-x^*}$ , where b minimizes the size of **R** and IBLT **J** in the next step. She sends **R** and *b*.
- 3: Sender: The sender passes all transaction IDs in the block through R. She sends all transactions that are not in  $R$  directly to the receiver (red area of Fig. [4\)](#page-4-0)

<span id="page-4-0"></span>

Figure 2: [Protocol 1] Passing m mempool transactions through S results in a FPs (in dark blue). A green outline illustrates  $a^* > a$  with  $\beta$ -assurance, ensuring IBLT I decodes.

Figure 3: [Protocol 2] Passing m transactions through S results in z positives, obscuring a count of  $x$  TPs (purple) and  $y$  FPs (in dark blue). From  $z$ , we derive  $x^* < x$  with  $\beta$ -assurance (in green).

Figure 4: [Protocol 2] From our bound  $m - x^* > m - x$  with  $\beta$ -assurance (in yellow), we can derive a bound for the false positives from S as  $y^* > y$  with  $\beta$ assurance outlined in green.

- 4: Sender: The sender creates and sends an IBLT J of all transactions in the block such that  $b + y^*$  items can be recovered from it. This size accounts for  $b$ , the number of transactions that falsely appear to be in **, and**  $y^*$ **, the** number of transactions that falsely appear to be in S.
- 5: Receiver: The receiver creates IBLT J ′ from the transaction IDs in Z. She decodes the subtraction of the two blocks,  $J \triangle J'$ . From the result, she adjusts set Z, validates the Merkle root, and the protocol concludes.

As in Protocol 1, we set  $b$  so that the summed size of  $$ and J is optimally small; see Section [3.3.1.](#page-4-1) We also derive closed-form solutions for  $x^*$  and  $y^*$ ; see Section [3.3.2.](#page-5-0)

#### <span id="page-4-4"></span>3.2.1 Mempool Synchronization.

With a few changes, Protocols 1 and [2](#page-3-2) can be used by two peers to synchronize their mempools. Instead of a block, the sender places his entire mempool in S and I. The receiver passes her mempool through S, adding any negatives to H, the set of transactions that are not in S. Some transactions that the sender does not have in his mempool will falsely pass through S, and these are identified by I (assuming that it decodes); these transactions are also added to H. If I does not decode, Protocol 2 is executed to find transactions in the symmetric difference of the mempools; all missing transactions among the sender and receiver are exchanged, including those in set H. The protocol is more efficient if the peer with the smaller mempool acts as the sender since S will be smaller. Section [5.3.2](#page-10-0) shows that the protocol is efficient.

# <span id="page-4-5"></span>3.3 Ensuring Probabilistic Data Structure **Success**

Cryptocurrencies allow no room for error: the header's Merkle root can be validated with an exact set of transactions only. Yet, Graphene is a probabilistic solution, and if its failure rate is high, resources are wasted on recovery. In this section, we

derive the parameters for Graphene that ensure a tunable, very high success rate.

#### <span id="page-4-1"></span>3.3.1 Parameterizing Bloom filter S and IBLT I.

Graphene sends the least amount of data over the network when the sum of the Bloom filter S and IBLT I is minimal. Let  $T = T_{BF} + T_I$  be the summed size of the Bloom filter and IBLT. The size of a Bloom filter in bytes,  $T_{BF}$ , with false positive rate  $f_S$  and *n* items inserted is  $T_{BF} = \frac{-n \ln(f_S)}{8 \ln^2 2}$  [\[11\]](#page-12-7). Recall that we recover up to  $a^*$  items from the IBLT, where  $a^* > a$ with  $\beta$ -assurance. As we show in Section [3.3.1,](#page-4-1)  $a^* = (1 + \delta)a$ , where  $\delta$  is parameterized by  $\beta$ . An IBLT's size is a product of the number of items recovered from a symmetric difference and a multiplier  $\tau$  that ensures recovery at a desired success rate. Therefore, given the cost of  $r$  bytes per cell,  $T_I$  is

<span id="page-4-2"></span>
$$
T_I = r\tau (1+\delta)a.
$$
 (1)

When we set  $f_S = \frac{a}{m-n}$ <br>and IBI T in bytes is , then the total size of the Bloom filter and IBLT in bytes is

$$
T(a) = \frac{-n\ln(\frac{a}{m-n})}{8\ln^2 2} + r\tau(1+\delta)a.
$$
 (2)

The value of *a* that minimizes *T* is either:  $a = 1$ ;  $a = m - n$ ; or the value of a where the derivative of Eq. [2](#page-4-2) with respect to a is equal to zero, which is

<span id="page-4-3"></span>
$$
a \approx n/(8r\tau \ln^2 2). \tag{3}
$$

Eq. [3](#page-4-3) is approximate as  $\delta$  is a function of a rather than a constant. The exact value is closed form but we omit it for clarity. Furthermore, implementations of Bloom filters and IBLTs involve non-continuous ceiling functions. As a result, Eq. [3](#page-4-3) is accurate only for  $a \ge 100$ ; otherwise the critical point a ′ produced by Eq. [3](#page-4-3) can be inaccurate enough that  $T(a')$  is as much as 20% higher than its true minimum value. Graphene exceeds the performance of previous work when Eq. [3](#page-4-3) is used to select a. However, implementations that desire strictly optimal performance should take an extra step.

If Eq. [3](#page-4-3) results in a value of a less than 100, its size should be computed using accurate ceiling functions and compared against all points  $a < 100$ .

Derivation of  $a^*$ . We can parameterize IBLT I based on the expected number of false positives from S, but to expect a high decode rate, we must account for the natural variance of false positives generated by S. Here we derive a closed-form expression for  $a^*$  as a function of a and  $\beta$  such that  $a^* > a$ holds with  $\beta$ -assurance, i.e.  $a^* > a$  with probability at least  $\beta$ . Define  $A_1, \ldots, A_{m-n}$  to be independent Bernoulli trials such that  $Pr[A_i = 1] = f_S$ ,  $A = \sum_{i=1}^{m-n} A_i$ , and  $\mu = E[A]$ .

<span id="page-5-1"></span>THEOREM 1: Let m be the size of a mempool that contains all n transactions from a block. If a is the number of false positives that result from passing the mempool through Bloom filter **S** with FPR  $f_S$ , then  $a^* \ge a$  with probability  $\beta$  with probability β when

$$
a^* = (1 + \delta)a,
$$
  
where  $\delta = \frac{1}{2}(s + \sqrt{s^2 + 8s})$  and  $s = \frac{-\ln(1 - \beta)}{a}$ . (4)

A full proof appears in Appendix [A.](#page-13-9) According to Theorem [1,](#page-5-1) if the sender sends a Bloom filter with FPR  $f_S = \frac{a}{m-n}$ , then  $x^2 + y^2 - 3x + 4y + 5 = 0$ <br>with β-assurance, no more than  $a^*$  false positives will be generated by passing elements from Z though S. To compensate for the variance in false positives, IBLT I is parametrized by a symmetric difference of  $a^* = (1 + \delta)a$  items. It will decode subject to its own error rate (see Section [4\)](#page-6-0), provided that  $a < a^*$  (which occurs with probability  $\beta$ ) and the receiver has all  $n$  transactions in the block. We evaluate this approach in Section [5.3;](#page-9-0) see Fig. [12.](#page-10-1)

#### <span id="page-5-0"></span>3.3.2 Parameterizing Bloom filter **R** and IBLT **J**.

**Parameterizing**  $\boldsymbol{b}$ **.** In Protocol 2, we select  $\boldsymbol{b}$  so that the summed size of  **and**  $**J**$  **is optimally small. Its derivation is** similar to *a*. We show below that  $y^* = (1 + \delta)y$ . Thus:

$$
T_2(b) = \frac{z \ln(\frac{b}{n-x^*})}{8 \ln^2 2} + r\tau(1+\delta)b.
$$
 (5)

The optimal value of  $b$  assuming continuous values is

$$
b \approx z/(8r\tau \ln^2 2). \tag{6}
$$

Similar to Section [3.3.1,](#page-4-1) an exact closed form of b exists and we omit it for clarity; and a perfectly optimal implementation would compute  $T_2(b)$  using ceiling functions for values of  $b < 100$ .

Using z to parameterize R and J. Here we offer a closedform solution to the problem of parameterizing Bloom filter **R** and IBLT J. This is a more challenging problem because  $x$ and y cannot be observed directly.

Let  $z$  be the observed count of transactions that pass through Bloom filter **S**. We know that  $z = x + y$ : the sum of  $x$  true positives and  $y$  false positives, illustrated as **purple** and dark blue areas respectively in Fig. [3.](#page-4-0) Even though  $x$  is unobservable, we can calculate a lower bound  $x^*$ , depending on x, z, m,  $f_S$  and  $\beta$ , such that  $x^* \leq x$  with  $\beta$ -assurance,<br>illustrated as a grass outline in Fig. 2. illustrated as a green outline in Fig. [3.](#page-4-0)

With  $x^*$  in hand, we also have, with  $\beta$ -assurance, an upper bound on the number of transactions the receiver is missing:  $n - x^* > n - x$ . This bound allows us to conservatively set  $f_R = \frac{b}{n-x^*}$  for Bloom filter **R**. In other words, since  $x^* < x$ <br>with  $\frac{a}{b}$  convence, the conday veing **P** will fail to send no with  $\beta$ -assurance, the sender, using **R**, will fail to send no more than b of the  $n - x$  transactions actually missing at the receiver. IBLT  $J$  repairs these  $b$  failures, subject to its own error rate (see Section [4\)](#page-6-0).

We also use  $x^*$  to calculate, with  $\beta$ -assurance, an upper bound  $y^* \geq y$  on the number of false positives that pass through S. The green area in Fig. [4](#page-4-0) shows  $y^*$ , which is a superset of the actual value for  $y$ , the dark blue area.

The sender's IBLT J contains all transactions in the block. The receiver's IBLT J' contains true positives from S, false positives from S, and newly sent transactions. Therefore, we bound both components of the symmetric difference by  $b + y^*$  transactions in order for the subtraction operation to decode. In other words, both J and J' are parameterized to account for more items than actually exist in the symmetric difference between the two IBLTs.

The following theorems prove values for  $x^*$  and  $y^*$ .

THEOREM 2: Let m be the size of a mempool containing  $0 \le x \le n$  transactions from a block. Let  $z = x + y$  be the count of mempool transactions that pass through  $S$ with FPR  $f_s$ , with true positive count x and false positive count y. Then  $x^* \leq x$  with probability  $\beta$  when

<span id="page-5-2"></span>
$$
x^* = \underset{x^*}{\arg\min} \ Pr[x \le x^*; z, m, f_S] \le 1 - \beta.
$$
\nwhere 
$$
Pr[x \le k; z, m, f_S] \le \sum_{i=0}^k \left( \frac{e^{\delta_k}}{(1 + \delta_k)^{1 + \delta_k}} \right)^{(m-k)f_S}
$$
\nand 
$$
\delta_k = \frac{z - k}{(m - k)f_S} - 1.
$$
\n(A full proof appears in Appendix A. (7)

<span id="page-5-3"></span>

THEOREM 3: Let m be the size of a mempool containing  $0 \le x \le n$  transactions from a block. Let  $z = x + y$  be the count of mempool transactions that pass through  $S$ with FPR  $f_S$ , with true positive count x and false positive

count *y*. Then *y*<sup>∗</sup> ≥ *y* with probability β when  
\n
$$
y^* = (1 + \delta)(m - x^*) f_S,
$$
\nwhere  $\delta = \frac{1}{2} (s + \sqrt{s^2 + 8s})$  and  $s = \frac{-\ln(1 - \beta)}{(m - x^*) f_S}.$  (8)  
\nA full proof appears in Appendix A.

**Special case:**  $m \approx n$ . When  $m \approx n$ , our optimization procedure in Protocol 1 will parameterize S and  $f_s$  to a value near 1, which is very efficient if the receiver has all of the block. But if  $m \approx n$  and the receiver is missing some portion of the block, Protocol 1 will fail. With  $z \approx m$ , Protocol 2 will set  $y^* \approx m$  and  $x^* \approx 0$ , and  $f_R \approx 1$ ; and most importantly, IBLT<br>**I** will be sized to m molting it legger than a regular block  $J$  will be sized to  $m$ , making it larger than a regular block.

Fortunately, resolution is straightforward. If Protocol 1 fails, and the receiver finds that  $z \approx m$ ,  $y^* \approx m$ , and  $f_R \approx 1$ ,<br>then in Step 2 of Protocol 2, the receiver should set f, to then in Step 2 of Protocol 2, the receiver should set  $f_R$  to a fixed value. We set  $f_R = 0.1$ , but a large range of values execute efficiently (we tested from 0.001 to 0.2). All mempool transactions are inserted into Bloom filter  $R$ , and  $R$  is transmitted to the sender.

The sender follows the protocol as usual, sending IBLT J along with  $h$  transactions from the block not in **. However,** he deviates from the protocol by also sending a third Bloom filter F intended to compensate for false positives from R. The roles of Protocol 2 are thus reversed: the sender uses Theorems 2 and 3 to solve for  $x^*$  and  $y^*$ , respectively, to bound false positives from  $\bf{R}$  (substituting the block size for mempool size and  $f_R$  as the FPR). He then solves for  $b$ such that the total size in bytes is minimized for F with FPR  $f_F = \frac{b}{m-h}$  and J having size  $b + y^*$ . This case may be common<br>when Crophone is used for mempool synchronization, our when Graphene is used for mempool synchronization; our evaluations in Fig. [14](#page-11-0) in Section [5.3.2](#page-10-0) show that this method is more efficient than Compact Blocks.

Alternatives to Bloom filters. There are dozens of variations of Bloom filters [\[35,](#page-12-21) [47\]](#page-13-5), including Cuckoo Filters [\[24\]](#page-12-26) and Golomb Code sets [\[27\]](#page-12-27). Any alternative can be used if Eqs. [2,](#page-4-2) [3,](#page-4-3) [5,](#page-5-2) and [6](#page-5-3) are updated appropriately.

## <span id="page-6-0"></span>4 ENHANCING IBLT PERFORMANCE

The success and performance of Graphene rests heavily on IBLT performance. Using IBLTs over a network has been studied in only a handful of papers [\[12,](#page-12-28) [23,](#page-12-10) [28,](#page-12-8) [38,](#page-12-29) [42\]](#page-13-7), and current results are generally asymptotic with the size of the IBLT (the notable exception is Eppstein et al. [\[23\]](#page-12-10), which we discuss in Section [2\)](#page-1-0). In this section, we contribute several important results that allow for IBLTs to be used in practical systems with reliable precision. IBLTs are deceptively challenging to parameterize so that *j* items can be recovered with a desired success probability of  $p$ , using the minimal number of cells. Only two parameters can be set: the hedge factor,  $\tau$  (resulting in  $c = i\tau$  cells total), and the number of hash

<span id="page-6-1"></span>

Figure 5: Parameterizing an IBLT statically results in poor decode rates. The black points show the decode failure rate for IBLTs when  $k = 4$  and  $\tau = 1.5$ . The blue, green and yellow points show decode failure rates of optimal IBLTs, which always meet a desired failure rate on each facet (in magenta). Size shown in Fig. [7.](#page-7-0)

functions, k, used to insert an item (each function ranges over  $c/k$  cells).

Motivation. Fig. [5](#page-6-1) motivates our contributions, showing the poor decode rate of an IBLT if static values for  $k$  and  $\tau$  are applied to small values of *j*. The figure shows three desired decode failure rates (1−p) in magenta: 1/24, 1/240, and 1/2400. The black points show the decode failure probability we observed in our IBLT implementation for static settings of  $\tau = 1.5$  and  $k = 4$ . The resulting decode rate is either too small from an under-allocated IBLT, or exceeds the rate through over-allocation. The colored points show the failure rates of actual IBLTs parameterized by the algorithm we define below: they are optimally small and always meet or exceed the desired decode rate.

## 4.1 Optimal Size and Desired Decode Rate

Past work has never defined an algorithm for determining size-optimal IBLT parameters. We define an implementationindependent algorithm, adopting Malloy's [\[40\]](#page-13-10) and Goodrich et al.'s interpretation [\[28\]](#page-12-8) of IBLTs as uniform hypergraphs.

Let  $H = (V, X, k)$  be a k-partite, k-uniform hypergraph, composed of c vertices  $V = V_1 \cup ... \cup V_k$  and j hyper-edges X, each connecting  $k$  vertices, one from each of the  $V_i$ . The hypergraph represents on IBIT with  $k$  head functions is hypergraph represents an IBLT with  $k$  hash functions,  $j$ inserted items, and  $c$  cells. Each cell corresponds to a vertex such that  $|V| = c$  and  $|V_i| = c/k$  (we enforce that c is divisible<br>by  $k$ ). Each item represents an adde connecting k vertices by  $k$ ). Each item represents an edge connecting  $k$  vertices, with the ith vertex being chosen uniformly at random from  $V_i$ . Vertices  $V_i$  represent hash function *i*, which operates over a distinct range of cells. The  $r$ -core [\[44\]](#page-13-11) of  $H$  is the maximal subgraph in which all vertices have degree at least

<span id="page-7-2"></span>

Figure 6: This algorithm finds the optimally small size of  $c =$  $j\tau$  cells that decodes  $j$  items with decode success probability  $p$ (within appropriate confidence intervals) from an IBLT with k hash functions. **decode** operates over a hypergraph rather than a real IBLT.

r. H contains a non-empty 2-core iff the IBLT it represents cannot be decoded.

We seek an algorithm for determining the most spaceefficient choice for  $c$  and  $k$  that is sufficient to ensure a decode rate of  $p$  for a fixed number of inserted items  $j$ . Items are inserted pseudo-randomly by applying the hash functions. Therefore, it makes sense to model the edge set  $X$  as a random variable. Define  $\mathcal{H}_{j,p} = \{(V, X, k) | E[{\sf decode}((V, X, k))] \geq$  $p, |X| = i$ , or the set of hypergraphs  $(V, X, k)$  on j edges whose expected decode success rate is bounded by  $p$ . Based on this definition, the algorithm should return

<span id="page-7-1"></span>
$$
\underset{(V,X,k)\in\mathcal{H}_{j,p}}{\arg \min} |V|.
$$
 (9)

Our approach for solving Eq. [9](#page-7-1) is to fix  $j$ ,  $p$ , and  $k$  and perform binary search over all possible values for  $c = |V|$ . Binary search is justified by the fact that the expected decode failure rate is a monotonically increasing function of  $c$ , which can explained as follows. A 2-core forms in  $(V, X, k)$  when there exists some group of  $v$  vertices that exclusively share a set of at least  $2v$  edges. Define vertex set  $U$  such that  $|U| > |V|$ . Since the j edges in X are chosen uniformly at random, and there are more possible edges on vertex set  $U$ , the probability that a given set of 2v edges forms in  $(U, X, k)$ must be lower than in  $(V, X, k)$ .

Fig. [6](#page-7-2) shows the pseudocode for our algorithm, which relies on two functions. The function decode(j,k,c) takes a random sample from the set of hypergraphs  $\mathcal{H}_{i,p}$  and determines if it forms a 2-core (i.e., if it decodes), returning True or False. The function conf\_int(s,t) returns the 2-sided

<span id="page-7-0"></span>

Figure 7: Size of optimal IBLTs (using Alg. 1) given a desired decode rate; with a statically parameterized IBLT ( $k = 4, \tau =$ 1.5) in black. For clarity, the plot is split on the  $x$ -axis. Decode rates are shown in Fig. [5.](#page-6-1)

confidence interval of a proportion of  $s$  successes and  $t$  trials. In practice, we call Alg. 1 only on values of  $k$  that we have observed to be reasonable (e.g., 3 to 15), and prune the search of each  $k$  when it is clear that it will not be smaller in size than a known result.

We have released an open-source implementation of IBLTs in C++ with a Python wrapper [\[5\]](#page-12-13). The release includes an implementation of Alg. 1 and optimal parameters for several decode rates. Compared to a version of our algorithm that uses actual IBLTs, our hypergraph approach executes much faster for all *j*. For example, to parameterize  $j = 100$ , our approach completes in 29 seconds on average (100 trials). Allocating actual IBLTs increases average run time to 426 seconds.

Fig. [7](#page-7-0) shows the size of IBLTs when parameterized optimally for three different decode rates. If parameterized correctly, the number of cells in an IBLT grows linearly, with variations due to inherent discretization and fewer degrees of freedom in small IBLTs.

#### 4.2 Ping-Pong Decoding

Graphene takes advantage of its two IBLTs to increase the decode rate for Protocol 2 in a novel fashion. IBLTs I and J are different sizes, and may use a different number of hash functions, but contain the same transactions. When an IBLT fails to decode completely, it still can succeed partially. The transactions that are decoded from J can be removed from I, and decoding I can be retried. Transactions from I can then be removed from J, and decoding J can be retried; and so on in a ping-pong fashion. We note that if the count of a decoded item is 1, then it should be subtracted from the other IBLT; if the count is -1, then it should be added to the other IBLT.

<span id="page-8-0"></span>

Figure 8: Decode rate of a single IBLT (parameterized for a 1/240 failure rate) versus the improved ping-pong decode rate from using a second, smaller IBLT with the same items.

The IBLTs should use different seeds in their hash functions for independence.

Fig. [8](#page-8-0) shows an experiment where we compared the decode rate of a single IBLT parameterized to be optimally small and recover  $j \in [10, 20, 50, 100]$  items with decode failure rate of  $1 - p = \frac{1}{240}$ . We then inserted the same items into a second IBLT parameterized to hold  $0 < i \le j$  items. When *i* is the same size as *j*, the failure rate is  $(1 - p)^2$  or lower. But improvements can be seen for values  $i < j$  as well. When  $j$  is small, very small values of  $i$  improve the decode rate. For larger values of j, larger values of i are needed for decoding. The use of ping-pong decoding on Graphene is an improvement of several orders of magnitude; results are presented in Fig. [17](#page-16-0) in Appendix [C.](#page-15-0)

This approach can be extended to other scenarios that we do not investigate here. For example, a receiver could ask many neighbors for the same block and the IBLTs can be jointly decoded with this approach.

## 5 EVALUATION

Our evaluation reaches the following conclusions:

- Graphene Protocol 1 is more efficient than using a Bloom filter alone, by  $\Omega(n \log n)$  bits. For all but small *n*, it is more efficient than deterministic solutions.
- We deployed Protocol 1 worldwide in Bitcoin Cash and show it performs as expected; and our implementation of Protocol 1 for Ethereum evaluated against historic data also shows expected gains.
- Using extensive Monte Carlo simulations, we show that Graphene Protocols 1 and 2 are always significantly smaller than Compact Blocks and XThin for a variety of scenarios, including mempool synchronization.

• In simulation, the decode success rates of Graphene Protocols 1 and 2 are above targeted values.

#### <span id="page-8-1"></span>5.1 Comparison to Bloom Filter Alone

The information-theoretic bound on the number of bits required to describe any unordered subset of *n* elements, chosen from a set of *m* elements is  $\lceil \log_2 {m \choose n} \rceil \approx n \log_2(m/n)$ bits [\[14\]](#page-12-30). Carter et al. also showed that an approximate solution to the problem has a more efficient lower bound of  $-n \log_2(f)$  bits by allowing for a false positive rate  $f$  [\[16\]](#page-12-19).

Because our goal is to address a restricted version of this problem, Graphene Protocol 1 is more efficient than Carter's bound for even an optimal Bloom filter alone. This is because Graphene Protocol 1 assumes all n elements (transactions) are stored at the receiver, and makes use of that information whereas a Bloom filter would not.

THEOREM 4: Relaying a block with n transactions to a receiver with a mempool (a superset of the block) of m transactions is more efficient with Graphene Protocol 1 than using an optimally small Bloom filter alone, when the IBLT uses  $k \geq 3$  hash functions. The efficiency gains of Graphene Protocol 1 are  $\Omega(n \log_2 n)$ .

A full proof appears in Appendix [B.](#page-15-1) Graphene cannot replace all uses of Bloom filters, only those where the elements are stored at the receiver, e.g., set reconciliation.

As m − n approaches zero, Protocol 1 shrinks its Bloom filter and approaches an IBLT-only solution. If we check the special case of Graphene having an FPR of 1 (equivalent to not sending a Bloom filter at all) then Graphene is as small as any IBLT-only solution, as expected; As  $m - n$  increases, Graphene is much smaller than sticking with an IBLT-only solution, which would have  $\tau(m - n)$  cells.

Graphene is not always smaller than deterministic solutions. As we show in our evaluations below, for small values of n (about 50–100 or fewer depending on constants), deterministic solutions perform better. For larger values, Graphene's savings are significant and increase with n.

We leave analytic claims regarding Protocol 2 for future work; however, below we empirically demonstrate its advantage over related work.

# 5.2 Implementations

Bitcoin Cash Implementation. We coded Graphene (Protocol 1) for Bitcoin Unlimited's Bitcoin Cash client at their request. It appeared first in edition 1.4.0.0 (Aug 17, 2018), as an experimental feature and since 1.5.0.1 (Nov 5, 2018) has been the default. Currently, 686 nodes (operated by persons unknown to us) are running Graphene on the Bitcoin Cash mainnet. An updated count of nodes can be found at [\[1\]](#page-12-31).

<span id="page-9-1"></span>

Figure 9: [Deployment on BCH, Protocol 1]: Performance of Protocol 1 as deployed on the Bitcoin Cash network. The node was connected to one other peer running the same code. The x-axis is split across two facets for clarity.

Figure 10: [Implementation, Protocol 1] An implementation of Protocol 1 for the Geth Ethereum client run on historic data. The left facet compares against Ethereum's use of full blocks; the right compares against an idealized version of Compact Blocks using 8 bytes/transaction.

Graphene is part of the formal plans for two major clients on Bitcoin Cash (BCH): Unlimited [\[4\]](#page-12-16) and ABC [\[3\]](#page-12-15).

Fig. [9](#page-9-1) shows results from our own peer running the protocol on the real network from January 9–31, 2019. Fig. [9](#page-9-1) also shows results from using Bitcoin Unlimited's XThin implementation; however, we have removed the cost of the receiver's Bloom filter to make the comparison fair (hence it is labelled XThin\*). As expected, while XThin\* costs grows quickly, the costs of Graphene are almost flat as block size increases. The cost of Graphene is not monotonically increasing because it can take advantage of an already-synchronized mempool, if available.

As of now, we have not deployed Protocol 2 (below we discuss our simulation of Protocol 2). Out of 3,151 Graphene blocks, all decoded successfully. This statistic also confirms our two-protocol approach: most of the time Protocol 1 is sufficient; and correcting failures with Protocol 2 is more rarely needed. In our deployment, we included several additional methods that improve decode rates. For example, the sender uses Bitcoin's filterInventoryKnown data structure to determine if an inv has not been sent or received for

all transactions in the block (in may be in-flight). And the sender compares the reported size of the receiver's mempool to pad out the IBLT slightly. The mechanisms are simple and practical.

Ethereum Implementation. We implemented Graphene for Geth, Ethereum's primary client software, and submitted a Pull Request [\[9\]](#page-12-12). We replayed all the blocks produced on the Ethereum mainnet blockchain on Jan 14, 2019 (a total of 5,672 blocks), introducing new message types to comply with Graphene's protocol. During our test, the size of the mempool at the receiver was kept constant at 60,000 transactions, which is typical (see [https://etherscan.io/chart/](https://etherscan.io/chart/pendingtx) [pendingtx\)](https://etherscan.io/chart/pendingtx). The left facet of Fig. [10](#page-9-1) shows the size in bytes of full blocks used by Ethereum and Graphene. The right facet compares Graphene (including transaction ordering information) against a line showing 8 bytes/per transaction (an idealization of Compact Blocks without overhead).

## <span id="page-9-0"></span>5.3 Monte Carlo Simulation

Methodology and Assumptions. We also wrote a custom block propagation simulator for Graphene (Protocols 1 and 2) that measures the network bytes exchanged by peers relaying blocks. We executed the protocol using real data structures so that we could capture the probabilistic nature of Bloom filters and IBLTs. Specifically, we used our publicly released IBLT implementation and a well-known Python Bloom filter implementation. In results below, we varied several key parameters, including the size of the block, the size of the receiver's mempool, and the fraction of the block possessed at the receiver. Each point in our plots is one parameter combination and shows the mean of 10,000 trials or more; if no confidence interval is shown, it was very small and removed for clarity. For all trials, we used a bound of  $β = 239/240$  (see Eqs. [18](#page-13-12) and [30\)](#page-15-2).

In all experiments, we evaluated three block sizes (in terms of transactions): 200, which is about the average size of Ethereum (ETH) and Bitcoin Cash (BCH) blocks; 2,000 which is the average size of Bitcoin (BTC) blocks; and 10,000 as an example of a larger block scenario. In expectation of being applied to large blocks and mempools, we used 8-byte transaction IDs for both Graphene and Compact Blocks. Also for Compact Blocks, we used getdata messages with block encodings of 1 or 3 bytes, depending on block size [\[17\]](#page-12-9).

#### 5.3.1 Graphene: Protocol 1.

Size of blocks. Fig. [11](#page-10-2) shows the cost in bytes of Graphene blocks compared to Compact Blocks. We focus on varying mempool size rather than block size. In these experiments, the receiver's mempool contains all transactions in the block plus some additional transactions, which increase along the  $x$ -axis as a multiple of the block size. For example, at fraction

<span id="page-10-2"></span>

Figure 11: [Simulation, Protocol 1] Average size of Graphene blocks versus Compact Blocks as the size of the mempool increases as a multiple of block size. Each facet is a block size: (200, 2000, and 10000 transactions). (N.b., This figure varies mempool size; Fig. [9](#page-9-1) varied block size.)

<span id="page-10-1"></span>

Figure 12: [Simulation, Protocol 1] Decode rate of Graphene blocks with a Chernoff bound of  $\beta = \frac{239}{240}$  (red dotted line), as block size and the number of extra transactions in the mempool increases as a multiple of block size.

0.5 and block size 2,000, the mempool contains 3,000 transactions in total. The experiments demonstrate that Graphene's advantage over Compact Blocks is substantial and improves with block size. Also, the cost of Graphene grows sublinearly as the number of extra transactions in the mempool grows.

Decode rate. Fig. [12](#page-10-1) shows the decode rate of Graphene blocks, as the mempool size increases. In all cases, the decode rate far exceeds the desired rate, demonstrating that our derived bounds are effective. Graphene's decode rate suffers when the receiver lacks the entire block in her mempool. For example, in our experiments, a receiver holding 99% of the block can still decode 97% of the time. But if the receiver holds less than 98% of the block, the decode rate for Protocol 1 is zero. Hence, Protocol 2 is required in such scenarios.

<span id="page-10-0"></span>5.3.2 Graphene Extended: Protocol 2.

<span id="page-10-3"></span>

Figure 13: [Simulation, Protocol 2] Graphene Extended cost as the fraction of the block owned by the receiver increases. Black-dotted line is the cost of Compact Blocks.

Our evaluations of Protocol 2 focus on scenarios where the receiver does not possess the entire block and  $m > n$ ; we evaluate  $m = n$  as a special case.

Size by message type. Fig. [13](#page-10-3) shows the cost of Graphene Extended, broken down into message type, as the fraction of the block owned by the receiver increases. The dashed line on the plot shows the costs for Compact Blocks, where the receiver requests missing transactions by identifying each as a 1- or 3-byte index (depending on block size) in the original ordered list of transactions in the block encodings [\[17\]](#page-12-9). (We exclude the cost of sending the missing transactions themselves for both protocols.)

Overall, Graphene Extended is significantly smaller than Compact Blocks, and the gains increase as the block size increases. For blocks smaller than 200, eventually Compact Blocks would be smaller in some scenarios.

Decode rate. Fig. [17](#page-16-0) in Appendix [C](#page-15-0) shows the decode rate of Graphene blocks; not only does it far exceed the desired rate, but approaches close to 100% with ping-pong decoding.

Not shown are our simulations of the Difference Digest by Eppstein et al. [\[23\]](#page-12-10), which is several times more expensive than Graphene. The Difference Digest is an IBLT-only solution that is an alternative to our Protocol 2. In that work, the sender begins by telling the receiver the value  $n$ . The receiver creates a Flajolet-Martin estimate [\[25\]](#page-12-32) of  $m - n$ , using  $\lceil \log_2(m-n) \rceil$  IBLTs, each with 80 cells where roughly m elements are inserted. The sender replies with a single IBLT of twice the number of cells as the estimate (to account for an under-estimate).

 $m \approx n$  and mempool synchronization. As described in Section [3.2.1,](#page-4-4) Graphene can be used for mempool synchronization, setting n to the size of the sender's mempool. In these cases, if peers are mostly synchronized, then  $m \approx n$ ,

<span id="page-11-0"></span>

Figure 14: [Simulation, Mempool Synchronization] Here  $m = n$  and the peers have a fraction of the sender's mempool in common on the x-axis. Graphene is more efficient, and the advantage increases with block and mempool size.

which is a special case for Graphene discussed in Section [3.3.1.](#page-4-1) Our evaluations of this scenario are shown in Fig. [14.](#page-11-0) In these experiments, the sender's mempool has n transactions, of which a fraction (on the x-axis) are in common with the receiver. The receiver's mempool size is topped off with unrelated transaction so that  $m = n$ . As a result, Protocol 1 fails and modifications from Section [3.3.1](#page-4-1) are employed. As with previous experiments, Graphene performs significantly better than Compact Blocks across multiple mempool intersection sizes and improvement increases with block size.

# 6 SYSTEMS ISSUES

## 6.1 Security Considerations

Malformed IBLTs. It is simple to produce an IBLT that results in an endless decode loop for a naive implementation; the attack is just as easily thwarted. To create a malformed IBLT, the attacker incorrectly inserts an item into only  $k - 1$ cells. When the item is peeled off, one cell in the IBLT will contain the item with a count of -1. When that entry is peeled,  $k - 1$  cells will contain the item with a count of 1; and the loop continues. The attack is thwarted if the implementation halts decoding when an item is decoded twice. Once detected, the sender can be dropped or banned by the receiver.

Manufactured Transaction Collisions. The probability of accidental collision of two 8-byte transaction IDs in a mempool of size *m* is ≈ 1 – Exp( $\frac{-m(m-1)}{2^{65}}$ ) [\[39\]](#page-12-33). An attacker may use brute force search to discover and submit collisions. SipHash [\[10\]](#page-12-34) is used by some blockchain protocols to limit the attack to a single peer.

With or without the use of SipHash, Graphene is more resilient against such collisions than XThin and Compact Blocks. Let  $t_1$  and  $t_2$  be transactions with IDs that collide with at least 8 bytes. In the worst case, the block contains  $t_1$ , the sender has never seen  $t_2$ , and the receiver possesses  $t_2$  but has never seen  $t_1$ . In this case, XThin and Compact Blocks will always fail; however, Graphene fails with low probability,  $f_S \cdot f_R$ . For the attack to succeed, first,  $t_2$  must pass through Bloom filter S as a full 32-byte ID, which occurs only with probability  $f_S$ . If it does pass, the IBLT will decode but the Merkle root will fail. At this point, the receiver will initiate Protocol 2, sending Bloom filter R. Second, with probability  $f_R$ ,  $t_1$  will be a false positive in **R** as a full 32-byte ID and will not be sent to the receiver.

#### 6.2 Transaction Ordering Costs

Bloom filters and IBLTs operate on unordered sets, but Merkle trees require a specific ordering. In our evaluations, we did not include the sender's cost of specifying a transaction ordering, which is  $n \log_2 n$  bits. As n grows, this cost is larger than Graphene itself. Fortunately, the cost is easily eliminated by introducing a known ordering of transactions in blocks. In fact, Bitcoin Cash clients deployed a Canonical Transaction Ordering (CTOR) ordering in Fall 2018.

# 6.3 Reducing Processing Time

Profiling our implementation code revealed that processing costs are dominated heavily by passing the receiver's mempool against Bloom filter S in Protocol 1. Fortunately, this cost is easily reduced. A standard Bloom filter implementation will hash each transaction ID  $k$  times  $-$  but each ID is already the result of applying a cryptographic hash and there is no need to hash  $k$  more times; see Suisani et al. [\[46\]](#page-13-13). Instead, we break the 32-byte transaction ID into k pieces. Applying this solution reduced average receiver processing in our Ethereum implementation from 17.8ms to 9.5ms. Alternative techniques [\[20,](#page-12-35) [21,](#page-12-36) [29\]](#page-12-37) are also effective and not limited to small values of k.

## 6.4 Limitations

Graphene is a solution for set reconciliation where there is a trade-off between transmission size, complexity (in terms of network round-trips), and success rate. In contrast, popular alternatives such as Compact Blocks [\[17\]](#page-12-9) have predictable transmission size, fixed transmission complexity, use a trivial algorithm, and always succeed. Graphene's performance gains increase as block size grows, but is a probabilistic solution with a (tunable) failure rate.

# 7 CONCLUSIONS

We introduced a novel solution to the problem of determining a subset of items from a larger set two parties hold in common, using a novel combination of Bloom filters and IBLTs. We also provided a solution to the more general case,

where one party is missing some or all of the subset. Specifically, we described how to parametrize the probabilistic data structures in order to meet a desired decode rate. Through a detailed evaluation using simulations and real-world deployment, we compared our method to existing systems, showing that it requires less data transmission over a network and is more resilient to attack than previous approaches.

#### <span id="page-13-9"></span>A THEOREMS FROM SECTION [3.3](#page-4-5)

For completeness, we provide the proof of a well-known version of Chernoff bounds that appears commonly in lecture notes, but not in any formal reference to our knowledge.

LEMMA 1: Let A be the sum of i independent Bernoulli trials  $A_1, \ldots, A_i$ , with mean  $\mu = E[A]$ . Then for  $\delta > 0$ 

$$
Pr[A \ge (1+\delta)\mu] \le Exp\left(-\frac{\delta^2}{2+\delta}\mu\right),\qquad(10)
$$

PROOF: Starting from the well-known Chernoff bound [\[39\]](#page-12-33):

$$
Pr[A \ge (1+\delta)\mu] \le \left(\frac{e^{\delta}}{(1+\delta)^{1+\delta}}\right)^{\mu} \tag{11}
$$

$$
= \exp(\mu(\delta - (1+\delta)ln(1+\delta))) \tag{12}
$$

$$
\leq \exp\left(\mu\left(\delta - (1+\delta)\left(\frac{2\delta}{2+\delta}\right)\right)\right) \tag{13}
$$

$$
= \exp\left(\frac{-\delta^2}{2+\delta}\mu\right) \tag{14}
$$

Above, we rely on the inequality  $ln(1 + x) \ge \frac{x}{1 + x/2} = \frac{2x}{2+x}$  for Above, we fely on the inequality  $ln(1 + x) \le \frac{1}{1 + x/2} - \frac{1}{2 + x}$  for  $x > 0$  (see [\[34\]](#page-12-38)), and that  $e^{a-b} \le e^{a-c}$  when  $b \ge c$ .

THEOREM 1: Let m be the size of a mempool that contains all n transactions from a block. If a is the number of false positives that result from passing the mempool through Bloom filter S with FPR  $f_S$ , then  $a^* \ge a$  with probability  $\beta$  when probability β when

$$
a^* = (1 + \delta)a,
$$
  
where  $\delta = \frac{1}{2}(s + \sqrt{s^2 + 8s})$  and  $s = \frac{-\ln(1 - \beta)}{a}$ . (15)

**PROOF:** There are  $m - n$  potential false positives that pass through S. They are a set  $A_1, \ldots, A_{m-n}$  of independent Bernoulli trials such that  $Pr[A_i = 1] = f_S$ . Let  $A = \sum_{i=1}^{m-n} A_i$  and  $\mu = E[A] = f_S(m-n) = \frac{a}{m-n}$  as From Lemma  $\mu = E[A] = f_S(m - n) = \frac{a}{m - n}(m - n) = a$ . From Lemma 1, we have

<span id="page-13-14"></span>
$$
Pr[A \ge (1 + \delta)\mu] \le \text{Exp}\bigg(-\frac{\delta^2}{2 + \delta}\mu\bigg),\tag{16}
$$

for  $\delta \geq 0$ . The receiver can set a bound of choice,  $0 < \beta < 1$ , and solve for  $\delta$  using the right hand side of Eq. [16.](#page-13-14) To bound with high probability, we seek the complement of the right hand side

$$
\beta = 1 - \exp\left(-\frac{\delta^2}{2 + \delta}a\right) \tag{17}
$$

<span id="page-13-12"></span>
$$
\delta = \frac{1}{2}(s + \sqrt{s^2 + 8s}), \text{ where } s = \frac{-\ln(1 - \beta)}{a}.
$$
 (18)

THEOREM 2: Letm be the size of a mempool containing  $0 \le x \le n$  transactions from a block. Let  $z = x + y$  be the count of mempool transactions that pass through  $S$ with FPR  $f_S$ , with true positive count x and false positive

count y. Then 
$$
x^* \le x
$$
 with probability β when  
\n
$$
x^* = \underset{x^*}{\arg \min} \ Pr[x \le x^*; z, m, f_S] \le 1 - \beta.
$$
\nwhere 
$$
Pr[x \le k; z, m, f_S] \le \sum_{i=0}^k \left( \frac{e^{\delta_k}}{(1 + \delta_k)^{1 + \delta_k}} \right)^{(m-k)f_S}
$$
\nand 
$$
\delta_k = \frac{z - k}{(m - k)f_S} - 1.
$$
\n(19)

 $\parallel$  and  $\infty$  (m − k) f<sub>S</sub>  $\cdot$  (n − k) f<sub>S</sub>  $\cdot$  (1.5) **PROOF:** We can't observe x or y, but whatever their real values are, we know their dependency:  $Y = \sum_{i=1}^{m-x} Y_i$ , where  $Y$ ,  $Y = Y$  are independent Bernoulli trials such that  $Pr[Y]$ .  $Y_1, \ldots, Y_{m-x}$  are independent Bernoulli trials such that  $Pr[Y_i =$  $1] = f_S$ .

For a given value x, we can compute  $Pr[Y \ge y]$ , the probability of at least  $y$  false positives passing through the sender's Bloom filter. We apply a Chernoff bound [\[39\]](#page-12-33):

$$
Pr[y; z, x, m] =
$$

$$
Pr[Y \ge (1 + \delta)\mu] \le \left(\frac{e^{\delta}}{(1 + \delta)^{1 + \delta}}\right)^{\mu} \qquad (20)
$$

where  $\delta > 0$ , and  $\mu = E[Y] = (m-x) f_S$ . By setting  $(1 + \delta)\mu = z - x$ and solving for  $\delta$ , we have

$$
(1+\delta)(m-x)f_S = z - x \tag{21}
$$

$$
\delta = \frac{z - x}{(m - x)f_S} - 1.
$$
 (22)

We substitute  $\delta$  into Eq. [20](#page-14-0) and bound the probability of observing a value of  $y = z - x$  or greater, given that the receiver has x transactions in the block. This realization allows us to enumerate all possible scenarios for observation  $z$ . The cumulative probability of observing  $y$ , parametrized by z, given that the receiver has at most  $k$  of the transactions in the block, is:

$$
Pr[x \le k; z, m, f_S] = \sum_{i=0}^{k} Pr[y; z, k, m]
$$
 (23)

$$
\leq \sum_{i=0}^{k} \left( \frac{e^{\delta_k}}{(1+\delta_k)^{1+\delta_k}} \right)^{(m-k)f_S} \tag{24}
$$

where  $\delta_k = \frac{z-k}{(m-k)f_s} - 1$ . Finally, using this closed-form equation, we select a bounding probability  $\beta$ , such as  $\beta = 239/240$ . We seek a probability  $\beta$  of observing  $z$  from a value  $x^*$  or larger; equivalently, we solve for the complement:

$$
\underset{x^*}{\text{arg min}} Pr[x \le x^*; z, m, f_S] \le 1 - \beta. \tag{25}
$$

To summarize,  $x^*$  is the *smallest* number of true positives such that the cumulative probability of observing  $y = z - x^*$ false positives is at least  $1 - \beta$ .

For good measure, we validated the theorem empirically, as shown in Fig. [15.](#page-14-1)

<span id="page-14-1"></span>

<span id="page-14-0"></span>Figure 15: [Simulation] The fraction of Monte Carlo experiments where  $x^* < x$  via Theorem 2 compared to a desired bound of  $\beta = 239/240$  (shown as a dashed red line).

<span id="page-14-2"></span>

Figure 16: [Simulation, Protocol 2] The fraction of Monte Carlo experiments where  $y^* > y$  via Theorem 3 compared to a desired bound of  $\beta = 239/240$  (shown as a dashed red line).

THEOREM 3: Letm be the size of a mempool containing  $0 \le x \le n$  transactions from a block. Let  $z = x + y$  be the count of mempool transactions that pass through  $S$ with FPR  $f_S$ , with true positive count x and false positive count y. Then  $y^* \geq y$  with probability  $\beta$  when

$$
y^* = (1 + \delta)(m - x^*)f_S,
$$
  
where  $\delta = \frac{1}{2}(s + \sqrt{s^2 + 8s})$  and  $s = \frac{-\ln(1 - \beta)}{(m - x^*)f_S}.$  (26)

**PROOF:** First, we solve for  $x^* \leq x$  with  $\beta$ -assurance using Theorem 2. We find  $y^* = z - x^* \ge y$  by applying Lemma 1 to  $Y = \sum_{i=1}^{m-x^*}$ , the sum of  $m - x^*$  independent Bernoulli trials  $\mu = \sum_{i=1}^{\infty}$ , the sum of  $m - x$  mode<br>pendent bernous such that  $Pr[Y_i = 1] = f_S$  trials and  $\mu = (m - x^*)f_S$ :

$$
Pr[Y \ge (1 + \delta)\mu] \le \text{Exp}\left(-\frac{\delta^2}{2 + \delta}\mu\right),\tag{27}
$$

for  $\delta \geq 0$ . We select  $0 < \beta < 1$ , and solve for  $\delta$  using the right hand side of Eq. [27.](#page-15-3) To bound with high probability, we seek the complement of the right hand side.

$$
\beta = 1 - \text{Exp}\left(-\frac{\delta^2}{2 + \delta}(m - x^*)f_S\right) \tag{28}
$$

$$
\delta = \frac{1}{2}(s + \sqrt{s^2 + 8s}), \text{ where } s = \frac{-\ln(1 - \beta)}{(m - x^*)f_S}. \tag{30}
$$

Then, we set

$$
y^* = (1 + \delta)(m - x^*)f_S.
$$
 (31)

Since,  $x^* \leq x$  with  $\beta$ -assurance, it follows that  $y^*$  also bounds the sum of  $m - x$  Bernoulli trials, where

$$
y^* = (1 + \delta)(m - x)f_S,
$$
 (32)

with probability at least  $\beta$  for any  $\delta \ge 0$  and  $m > 0$ .

We validated this theorem empirically as well, as shown in Fig. [16.](#page-14-2)

## <span id="page-15-1"></span>B THEOREMS FROM SECTION [5.1](#page-8-1)

THEOREM 4: Relaying a block with n transactions to a receiver with a mempool (a superset of the block) of m transactions is more efficient with Graphene Protocol 1 than using an optimally small Bloom filter alone, when the IBLT uses  $k \geq 3$  hash functions. The efficiency gains of Graphene Protocol 1 are  $\Omega(n \log_2 n)$ .

**PROOF:** We assume that  $m = cn$  for some constant  $c >$ 1. Our proof is asymptotic. Thus, according to the law of large numbers, every value  $\delta > 0$  (where  $\delta$  is defined as in Theorem [1\)](#page-5-1) is sufficient to achieve  $β$ -assurance when choosing values for  $a^*$ ,  $x^*$ , and  $y^*$ . Accordingly, we may proceed under the assumption that  $\delta = 0$ , i.e. there is no need to lower the false positive rate of either Bloom filter to account for deviations because the observed false positive rate will always match its expected value asymptotically.

<span id="page-15-3"></span>Let f, where  $0 < f < 1$ , be the FPR of a Bloom filter created in order to correctly identify  $n \geq 1$  elements from a set of  $m \geq 1$  elements. The size of the Bloom filter that has FPR,  $f$ , with *n* items inserted, is  $-n \log_2(f)$  bits [\[16\]](#page-12-19). Let  $f = \frac{p}{m-n}$ , where  $0 \leq p \leq 1$ . The expected number of false positives that can pass through the Bloom filter is  $\left(\frac{m-n}{(m-n)}\right)^{-p} = p$ . Since  $0 < p < 1$ , one out of every  $1/p$ <br>Bloom filters is expected to fail Bloom filters is expected to fail.

<span id="page-15-2"></span>To correctly identify the same set of items, Graphene instead uses a Bloom filter with  $f = \frac{a}{m-n}$ , where we set  $a = n/rt$  since the Bloom filter is optimal, and use an IBLT with  $a\tau$  cells (r bytes each) that decodes with probability p. The expected number of false positives that pass through Graphene's Bloom filter is  $(m - n) \frac{a}{(m-n)} = a$ . An IBLT with 1 to *a* items inserted in it decodes with probability  $1 - p$ . In other words, one out of every  $1/p$  Graphene blocks is expected to fail.

The difference in size is

$$
-n\log_2\left(\frac{p}{m-n}\right) - \left(-n\log_2\left(\frac{a}{m-n}\right) + ar\tau\right) \tag{33}
$$

$$
=n\log_2(a/p)-ar\tau\tag{34}
$$

$$
=n(\log_2 n + \log_2 1/pr) - 1)
$$
\n(35)

<span id="page-15-4"></span>
$$
= n(\log_2 n + \Omega(\tau^{2-k}))\tag{36}
$$

$$
=\Omega(n(\log_2 n)),\tag{37}
$$

where Eq. [36](#page-15-4) follows from Theorem 1 from Goodrich and Mitzenmacher [\[28\]](#page-12-8), given that we have an IBLT with  $k \geq 3$ hash functions.  $\Box$ 

# <span id="page-15-0"></span>C FIGURES FOR SECTION [5.3](#page-9-0)

Fig. [17](#page-16-0) shows the decode rate of Protocol 2 when the receiver is missing some fraction of the block, for block sizes of 200, 2000 and 10,000. Note that with the use of ping-pong decoding, the decode rate increases to almost 100%.

<span id="page-16-0"></span>

Figure 17: [Simulation, Protocol 2] Decode rate of Graphene blocks with a Chernoff bound of  $\beta = \frac{239}{240}$ , shown by the red dotted line, as block size and the number of extra transactions in the mempool increases. Error bars represent 95% confidence intervals.
